70. Human–Robot Augmentation

Massimo Bergamasco, Hugh Herr

The development of robotic systems capable of sharing with humans the load of heavy tasks has been one of the primary objectives in robotics research. At present, in order to fulfil such an objective, a strong interest in the robotics community is collected by the so-called wearable robots, a class of robotics systems that are worn and directly controlled by the human operator. Wearable robots, together with powered orthoses that exploit robotic components and control strategies, can represent an immediate resource also for allowing humans to restore manipulation and/or walking functionalities.

The present chapter deals with wearable robotics systems capable of providing different levels of functional and/or operational augmentation to the human beings for specific functions or tasks. Prostheses, powered orthoses, and exoskeletons are described for upper limb, lower limb, and whole body structures. State-of-the-art devices together with their functionalities and main components are presented for each class of wearable system. Critical design issues and open research aspects are reported.

70.1 Concept and Definitions

Since early developments, one of the primary objectives of technology has been that of relieving humans from heavy tasks [70.1]. The concept of human–robot augmentation refers to the use of robotics systems to increase human functionalities in different operational contexts [70.2]. In general, the augmentation of humans' performances through the use of robotic systems refers solely to the increase in mechanical capabilities involving motion control and generation of scaled levels of forces. Although complex operations involve and exploit perceptual capabilities, in this chapter the concept of human–robot augmentation is not referred to perceptual functionalities only. Examples of working conditions in which human–robot augmentation can play an essential role for the completion of the task can be considered, e.g., operations for debris removal after an earthquake in which human operators, wearing such systems, can move and operate in a more flexible and accurate way with respect to machines like cranes or excavators.

Other scenarios are represented by tasks in which the number of repetitions, instead of level of loads to be operated, is high and becomes the critical factor for decreasing fatigue, thus maintaining long-term levels of humans' safety.

By definition, wearable robots follow the human operator's movements and in this way can inherently and fully exploit human's dexterity, thus assuring a higher level of flexibility in addressing a specific task with respect to usual loading machines. A first and fundamental characteristic, and at the same time a strict design constraint, of wearable robots is the condition of possessing a physical structure which is always in contact with the human operator's body during operation. As a consequence, wearable robots design must take into account both biomechanics and human motor control aspects.

Research on wearable robots has received a strong contribution from the development of haptic interfaces, i.e., robotic systems that are able to generate forces on the human body (force feedback) while maintaining a high level of naturalness of user's movements. The development of haptic technologies in the last two decades has focused on the importance of designing robotic systems able to generate forces at the level of the hand or other parts of the human body. As a consequence, an increased attention of the scientific robotic community toward wearable robots has been recorded. In fact, most of the recent developments on robotic

exoskeletons derive from their application in neurorehabilitation [70.3], where the robotic system is used to kinetically assist the patient's limb during the performance of specific exercises.

The augmentation of human performances can be achieved with different types of robotic systems, e.g. from teleoperated robots to self-standing robotic systems amplifying human actions. Examples of robotic systems directly operated by the human operator are the Cobot system [70.4] and the intelligent autonomous system (IAS) [70.5]. However, in the framework of the present review work, the analysis is performed by considering only robotic systems that can be worn by the user.

At present, few definitions of wearable robotic systems have been considered. Herr makes a first classification between serial and parallel system [70.6].

Serial systems are considered those that increase the length and reachability of a limb, while parallel structures contribute to the effective augmentation of torques and forces generated by the human limb. Serial systems perform their action by exploiting elastic components integrated in their structure, thus not requiring a specific computer-based control system. Other classes of wearable robotic systems can be considered the so-called *hybrid* wearable systems, i.e., parallel robotic structures worn by the human operator in which the command for their motion is achieved by FES (functional electric stimulation). In this way, the control of the robotic structure is limited and does not allow a complete force control by the user [70.7]. Hybrid systems are not considered in this chapter.

Wearable robotics systems for human augmentation can be divided into three different categories: (i) prostheses, for the functional replacement of human limbs; (ii) powered orthoses, whose function is to actively operate in parallel with unhealthy human joints; and (iii) robotic exoskeletons that operate in parallel with human limbs [70.8].

The design of the above three types of robotic systems shows different approaches whether they are referred to upper, lower limbs, or to the whole body, respectively. In the following, the analysis of wearable robotic systems is given by considering present achievements in terms of devices, robotic components utilized for the actuation, control systems architectures, and devised application domains in which they are presently utilized.

70.2 Upper Limb Wearable Systems

Upper limb exoskeletons (ULEs) are wearable robots that are placed in parallel and work in concert with the human arm. Wearer's motions that fall within ULEs coverage are shoulder elevation/depression and retraction/protraction which are provided by the human's sterno-clavicular articulation; shoulder flexion/extension, abduction/adduction and medial/lateral rotation which are provided by the human's gleno-humeral articulation; elbow flexion/extension which is provided by the human's humero-ulnar articulation; forearm prono/supination which is provided by the human's radio-ulnar articulation; wrist flexion/extension and radial/ulnar deviation which are provided by the human's radio-carpal, mid-carpal, and intra-carpal articulations; and finger abduction/adduction and flexion/extension which are provided by the human's metacarpo-phalangeal and inter-phalangeal joints.

Proposed usages of ULEs are as rehabilitation devices, motion assists, human power/force amplifiers, and haptic interfaces. Depending on the specific application, the available ULEs differ in location of placement, number of degrees of freedom (DOFs) and their subdivision between active and passive DOFs, type of kinematic architecture and implementation, type of actuators and power transmission methods, types of sensorization, and number and place of connection points between ULE and wearer.

70.2.1 Location of Placement

With regard to location of placement, a number of systems have been developed which differ from the type of segments they can cover; for instance shoulder–elbow–wrist–finger complex [70.10, 11], shoulder–elbow–finger complex [70.9] (Fig. 70.1), shoulder–elbow–

Fig. 70.1 Upper limb exoskeletons for the shoulder–elbow–wrist–finger complex (PERCRO-II, L-Exos, after [70.9])

wrist complex [70.12–16] (Fig. 70.2), shoulder–elbow–forearm complex [70.17–20] (Fig. 70.3), shoulder–elbow complex [70.21–27] (Fig. 70.4), elbow–wrist complex [70.28, 29], wrist–finger complex [70.30], and the hand (fingers only) [70.31–33].

70.2.2 Degrees of Freedom

With regard to DOFs, developed systems largely differ depending on the specific location of placement. In particular, exoskeletons with up to 9-DOFs have been developed for the shoulder–elbow–wrist–finger complex [70.16], whereas exoskeletons with up to 18-DOFs have been developed for the wrist–finger complex [70.30].

Focusing on ULEs covering at least the shoulder–elbow–forearm complex, the developed systems typically feature [70.9–13, 15–20] the following: three active DOFs for shoulder flexion/extension, abduction/adduction and medial/lateral rotation; one active DOF for elbow flexion/extension; and one DOF, either active or passive, for forearm prono/supination.

Fig. 70.2a–c Upper limb exoskeletons for the shoulder–elbow–wrist complex: (a) RUPERT (after [70.14]); (b) ARMIN (after [70.15]); (c) SUEFUL-7 (after [70.16])

Fig.70.3a–d Upper limb exoskeletons for the shoulder–elbow–forearm complex: (a) PERCRO-I (after [70.34]); (b) MGA (after [70.19]); (c) PERCRO-III (after [70.9]); (d) RehabExos (after [70.20])

Some of these systems are also provided with a wrist having two active DOFs for flexion/extension and radial/ulnar deviation [70.10, 12, 13, 16]; an active [70.11, 15, 19, 23] or passive [70.26] DOF for shoulder elevation/depression (some systems also exist in which shoulder elevation/depression is coupled to shoulder abduction/adduction [70.15, 16, 35]); and an active [70.23] or passive [70.11, 26] DOF for shoulder retraction/protraction. Although the availability of ergonomic evaluation data is still limited, the inclusion of shoulder elevation/depression is deemed necessary for large-range-of-motion ULEs with arm elevation angles larger than 60° [70.15].

70.2.3 Kinematic Architecture and Implementation

Despite a few ULEs [70.10, 12, 26], the majority of the developed systems feature a kinematic architecture that is isomorphic to that of the wearer's upper limb (which means that the rotation axes of ULE joints are coaxial to those of the wearer's articulations). This choice usually reduces the chances of wearer–exoskeleton interference and enables the wearer to be connected to the ULE at different points over multiple links. With regard to implementation, different solutions have been proposed depending on the considered ULE articulation. In particular, three shoulder rotations have been implemented in the following different ways: (1) via three standard revolute pairs with either nonintersecting axes [70.10, 26, 26, 36] or with axes intersecting away from the center of the wearer's gleno-humeral articulation [70.12], which leads to sys-

tem designs that are not isomorphic with the wearer's limb kinematics; (2) via three standard revolute pairs with axes intersecting at the center of the wearer's gleno-humeral articulation [70.19, 23], which usually leads to ULEs with either limited range of motion or excessive encumbrance; (3) as in (2) but with the last revolute joint being a circular guide [70.9, 11, 13, 16, 20, 37], which enables for a more compact design that is, however, affected by a limited singularity-free workspace; (4) as in (2) but with the second revolute joint being a circular guide [70.38], which provides both a very compact design and a rather wide singularity-free workspace. Regarding the additional DOFs at the shoulder, both elevation/depression and retraction/protraction motions have been implemented via either revolute [70.19, 23] or prismatic [70.11, 15, 26] pairs. Elbow flexion/extension has been implemented almost univocally via a standard revolute pair. As for the wrist, flexion/extension and radial/ulnar deviation have been implemented by using two revolute joints with either intersecting axes [70.10, 12, 13] or slightly off-set axes [70.16]. In fact, in the human wrist, the radial/ulnar deviation axis passes distally with respect to the flexion/extension axis by approximately 5 mm.

70.2.4 Actuation and Power Transmission Methods

Actuation methods have also been quite variegated. Besides passive systems employing springs (or elastic bands) [70.22] and hydraulic disk brakes [70.26], ULEs have been equipped with hydraulic motors [70.10], pneumatic cylinders [70.24], pneumatic muscles [70.12, 14], and electric motors. Hydraulic motors provide very large power-to-weight ratio, high stiffness, and direct-drive operation; however, they feature low energetic efficiency and require bulky, high-pressure fluid components (power supply, valves, and tubing). Pneumatic cylinders and muscles provide large power-to-weight ratio and direct-drive operation; however they feature low energetic-efficiency, low stiffness, slow and nonlinear response, and require bulky and noisy fluid components (power supply, valves and tubing). In addition, pneumatic muscles can generate forces in one direction only, and thus they need to be used in an agonist–antagonist arrangement [70.12]. Electric motors are very efficient, easy to control, and have good power-to-weight ratio; however, they work better at high speeds. In the existing ULEs, electric motors are rarely used in direct-drive operation, but rather they are combined with either standard gearboxes (with spur [70.16] or planetary [70.9] gear-heads) or harmonic drives [70.19, 20, 27].

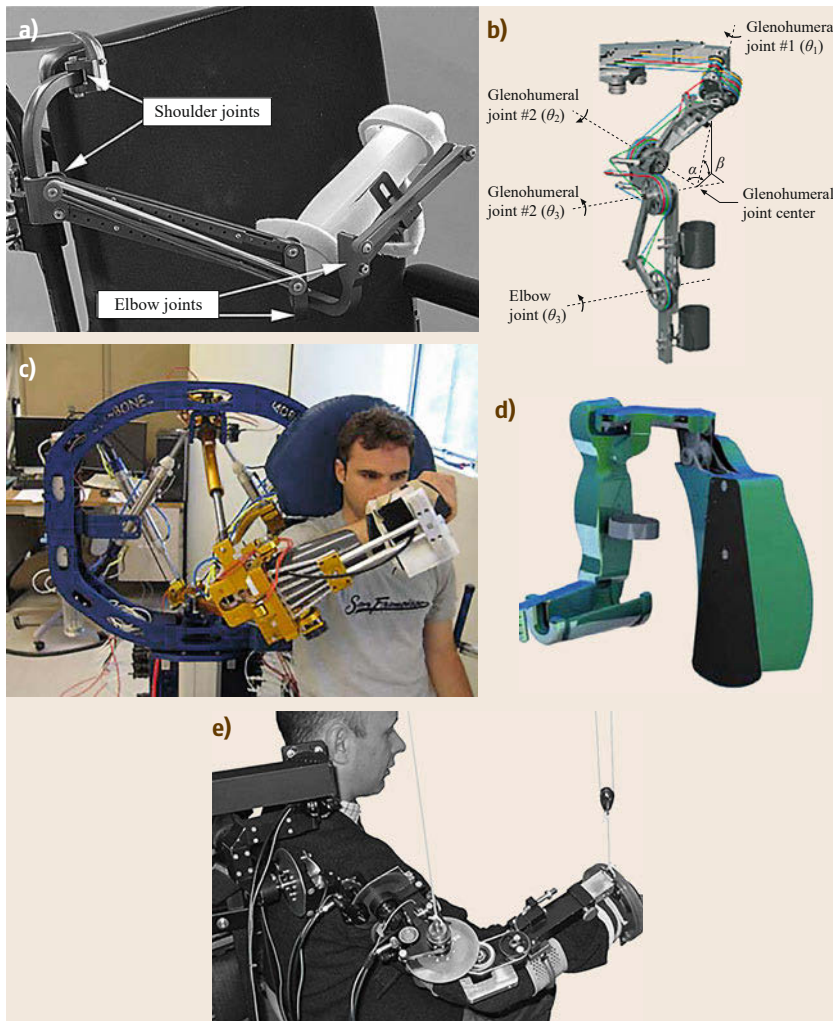

Fig.70.4a-e Upper limb exoskeletons for the shoulder-elbow complex: (a) WREX (after [70.22]); (b) MEDARM (after [70.23]); (c) BONES (after [70.24]); (d) ABLE (after [70.25]); (e) DAMPACE (after [70.26])

In the existing ULEs, hydraulic motors and pneumatic muscles have been located directly across single exoskeleton joints [70.10, 12, 14], whereas pneumatic cylinders have been used in an in-parallel arrangement to activate multiple joints [70.24]. Instead, electric motors have been placed either at the joints [70.19, 20] or in a remote location [70.9, 13, 23] (usually in the ULE base frame). This second choice has been made primarily in order to reduce the weight and inertia of moving exoskeleton parts, which enables the use of smaller motors and minimizes the disturbances on the wearer's natural motions.

ULEs with remotely placed actuators require appropriate transmission systems to transfer the power from the actuators to the joints. Except from specific cases [70.15, 23, 35] in which transmission linkages and timing belts have been used, the common

power transmission solution for ULEs has consisted in cable-drive systems, either closed-ended [70.9, 13] or open-ended [70.23]. Closed-ended transmissions require long cables, whereas open-ended transmissions require more motors than the number of actuated DOFs. Both open- and closed-ended cable-drive systems are lightweight, highly efficient, and back-drivable; thus they are very good solutions to transmit mechanical power over long distances. In addition, cable drives enable the easy implementation of speed-reduction stages, which should be placed as close as possible to the joint in order to maximize overall transmission stiffness [70.9]. Moreover, cable-drive transmissions spanning multiple joints make it possible to distribute loads across several cables, which can be used to minimize the torque requirements of the actuators [70.23].

70.2.5 Type of Sensorization

Apart from few passive systems only conceived as weight compensation devices [70.39], all the developed **ULEs** are equipped with position sensors (potentiometers or encoders), which are placed at the motors and/or at the joints so as to make it possible to estimate/control the overall system configuration. Besides, the considered **ULEs** largely differ from the point of view of force/torque sensorization. Thanks to the intrinsic low friction and high back-drivability, exoskeletons with cable-drives have been designed to operate without the need of force/torque sensors [70.9, 13, 23]. All the other **ULEs** are instead equipped with this kind of sensorization, which can be either concentrated at the points of connection with the wearer [70.11, 15, 16, 19] or distributed at every **ULE** joint [70.20]. The use of torque sensors distributed at every **ULE** joint enables for multicontact force control at multiple points distributed over multiple links and, additionally, makes it possible to design very robust force-feedback controllers that are rather insensitive to exoskeleton link variable inertia, transmission compliance, friction losses, actuator torque ripples, and gear teeth wedging actions [70.20]. The use of multi-DOF force/torque sensors concentrated at the points of wearer-**ULE** interaction makes the use of the exoskeleton less flexible and the controller less robust, but enables for a more accurate estimation and control of the endpoint forces that are exchanged with the wearer. In general, **ULEs** equipped with force/torque sensorization provide better haptic feedback than those relying on cable-drive transmissions only.

70.2.6 Hand Exoskeletons

The functionality of hand exoskeletons (**HE**) consists in exerting programmable forces on human fingers. Hand exoskeletons can be classified in two functional categories depending on the capability of exerting forces on a single phalanx (usually the distal phalanx correspondent to the fingertip) or on multiple phalanges (Fig. 70.5).

Multiphalanx hand exoskeletons (**MPHE**) are devices able to exert different forces on at least two of the phalanges of the same finger: usually the force can be applied on a fixed direction normal to the phalanx axis and belonging to the medial plane of the finger.

Single-phalanx hand exoskeletons (**SPHE**) are able to exert forces on one phalanx of the finger, usually the distal one only; some devices are able to generate a force only along a fixed direction but more commonly they can exert forces with any desired orientation.

Fig. 70.5 (a) Multiphalanx and (b) single-phalanx scheme for hand exoskeletons

Another taxonomy of hand exoskeletons considers two other categories:

- Anthropomorphic devices: the kinematics of the **HE** is morphologically similar to the human fingers
- Nonanthropomorphic devices: the kinematics is morphologically different from the human fingers.

The scientific literature in the last 30 years reports many works dealing with different **HE** designs mainly addressing three application fields: (1) teleoperation and virtual environments in which the **HE** are utilized as master controllers providing force feedback or for generating illusory forces to the hand of the human operator; (2) neurorehabilitation, in which **HE** are used for restoring hand functionalities after strokes or other neural impairments; (3) space applications in which **HE** are employed as active devices for extending grasping forces of the astronauts in extra vehicular activities.

The first known example of **HE** was introduced in the field of teleoperation by *Zarudiansky* back in 1981 [70.40]. The inventor has registered a patent for a tele-manipulation system equipped with a master device able to provide force feedback on different phalanges of the human hand. At the Jet Propulsion Laboratory Pasadena (**JPL**) in 1988, *Jau* [70.41] built a complete teleoperated master/slave system comprehending a hand exoskeleton device for four fingers. In the same years *Burdea* et al. developed a pneumatic actuated hand force feedback device [70.42], called Rutgers Master, able to exert a single force to the distal phalanx along a direction dependent on the kinematics of the device and on the position of the finger. *Bergamasco* [70.37] developed a four-finger **MPHE**. A nonanthropomorphic device was realized by *Koyama* et al. at Keyo University; this device is a three-finger exoskeleton for thumb, index, and middle finger with passive clutches actuation [70.43]. Such a device is anchored at the user's wrist and is able to exert forces in every direction belonging to the sagittal plane

of the fingers. *Frisoli et al.* [70.9] developed another nonanthropomorphic **HE**, called Pure Form Hand-Exos for virtual environment (**VE**) applications that features a very complex steel cable transmission studied for an optimal use of motor torque. *Nakagawara et al.* [70.44] built a device integrating the concept of encountered haptics: the device possesses 1-**DOF** for each finger and it is able to track the finger without any contact (even at the fingertip) through a noncontact sensor placed in correspondence of the nail. When contact is detected in the remote/virtual environment, a plate is moved against the user's fingertip. Another example of anthropomorphic hand exoskeleton for **VE** applications has been developed by *Fontana et al.* [70.32] with the aim of maximizing force accuracy and resolution (Fig. 70.6).

Other examples of **HEs** have been developed for medical applications. In this field, **HEs** are employed for rehabilitation procedures or as power-assisting devices (orthoses). In rehabilitation procedures a **HE** is commonly used for exerting forces (or trajectories) and, at the same time, measuring velocities and positions (or force) of the fingers. *Gomez et al.* [70.45] have integrated the Rutgers Master in a **VE** rehabilitation system. *Wege et al.* [70.46] developed a 4-**DOF HE** with a modular structure, actuated by Bowden cables. *Mulas et al.* [70.47] realize a **HE** that makes use of electromyography (**EMG**) signals for predicting the movements of the user finger. *Ito et al.* [70.48] built a complex **HE** for rehabilitation purposes with 4-**DOF** for the index, medium, and ring fingers and 5-**DOF** for the thumb, able to exert controlled torque on each phalanx.

HEs can implement the functionality of supporting people with permanent disabilities to perform common activities for daily living (**ADL**). Such devices, called hand orthoses or assistive **HE**, are controlled as power extenders allowing the user to exert only a fraction of the force required to accomplish the task. The first orthosis for the finger was developed by *Brown et al.* [70.49]. The realized device was a **HE** composed by three rings attached on the phalanges that were actuated with pulling cables. Other examples of hand orthoses are described in [70.4, 39]. Another field where **HEs** have proved their usefulness is in assisting astronauts in performing **EVA** (extra-vehicular activities). Due to the pressure difference, the suits that the astronauts wear during **EVA** require high force to be bended and represent a major constraint especially for manipulative tasks. For this reason, custom-designed **HEs**

Fig.70.6a,b Hand exoskeleton (after [70.32]) (a) without and (b) with tracking system

are used as an active tool to overcome the stiffness of the gloves. *Shields et al.* [70.50] developed the first **HE** for space applications. Such a device was an anthropomorphic **HE** with three active fingers; the thumb was excluded and the little finger was connected together with the ring finger. The **HE** has two **DOFs** for each finger and exploits a special mechanisms for the implementation of the finger flexion joints. The anthropomorphic kinematics is obtained through remote center of rotation joints. In 2001, *Yamada et al.* [70.51] developed, for the same space applications, another simplified **HE** called Skill Mate in which only the first flexion **DOF** of each finger is actuated. The **HE** developed by *Wang et al.* [70.52] is still utilized for the simulation and evaluation of different space gloves. The device features a kinematics implementation that is close to the **HE** developed by Shields but in this case the device has three **DOFs** coupled in a way that only one actuator is needed for each finger. Also in this case, flexion joints are implemented through remote center of rotations allowing the **HE** joints to closely correspond with the natural joints (metacarpophalangeal **MCP**, interphalangeal **IP**, distal **D**) of the human hand.

In general, it can be observed that **HEs** realized for **VE** and teleoperation have several mechanical features that are not present in the devices conceived for rehabilitation, **ADL** or **EVA** applications. **VE** and teleoperation application require in fact the simulation of fine haptic interaction and generally more demanding performances are needed in terms of mechanical features. In **VE** and teleoperation, the design of **HE** requires to minimize friction, inertia, and weight. On the other side, in other applications, a higher level of friction can be tolerated, allowing the use of Bowden cables for delocalizing the motors, or a simplified kinematic structure can be acceptable allowing exerting forces with less accuracy.

70.3 Lower Limb Wearable Systems

Lower extremity autonomous wearable robotics is a general classification covering actuated leg prostheses, orthoses, and exoskeletons.

70.3.1 Lower Extremity Autonomous Wearable Robotics

These robots are defined as active mechanical devices that are worn on a wearer's legs, and work in concert with the wearer's movements, either as permanent assistive devices for persons suffering from leg pathology, or augmentative devices for persons having *normal* physiological leg function. In general, the classification *active leg orthosis* is typically used to describe a device that is used to increase the capacity of a person suffering from leg pathology to ambulate, whereas the classification *leg exoskeleton* is used to describe a device that augments the locomotory performance of an able-bodied wearer. However, the classification *leg exoskeleton* has also been used to describe certain assistive devices that span in parallel across the entirety of the human leg [70.6]. Autonomous wearable leg robots are used as assistive interventions in the treatment of leg disabilities caused by amputation, stroke, cerebral palsy, and multiple sclerosis. In the realm of human augmentation, leg exoskeletons have been constructed for load-carrying augmentation, to improve the economy of walking or running, or to decrease musculoskeletal stress [70.6].

Since robots within this classification are worn by the wearer, it is critical that their design resemble biological leg function, both morphologically and neurologically. For this discussion on lower extremity wearable robotics, we use the term *bionic* to refer to an electromechanical structure designed to emulate, or extend, normal physiological function. A long-standing goal in robotic science is to apply neuromechanical principles of human movement to the development of highly functional wearable leg robotics [70.53]. Critical to this effort is the development of actuator technologies that behave like muscle, device architectures that resemble the body's own musculoskeletal leg design, and control methodologies that exploit principles of biological leg movement. In the next section, we present a computational model of human walking that unifies muscle and joint biomechanics with whole-body metabolism for level-ground walking at self-selected speed. The model underscores critical design principles for wearable leg robotics, including the importance of tendon-like compliance and reflexive control on locomotory performance – discussed in detail in Sect. 70.3.6. These design principles are discussed in

detail and then, by way of example, used to analyze the design of a bionic transtibial prosthesis. The chapter concludes with a discussion on critical areas for future research.

70.3.2 Neuromechanical Basis for Wearable-Robotic Leg Design

By understanding the underlying mechanisms that govern individual muscle–tendon behaviors in human locomotory function, roboticists can better design wearable robots that seamlessly integrate dynamically with the biological leg. To this end, in this section we present a computational model of human walking [70.54] that unifies muscle and joint biomechanics with whole-body metabolism for level-ground walking at self-selected speed. The model, shown in Fig. 70.7, comprises ankle, knee, and hip joints connected by rigid bodies representing the human trunk and two, three-segment legs. In the model, muscle–tendon units that dorsiflex the ankle, and flex and extend the knee, are assumed to act as linear springs upon neural activation; each muscle–tendon is modeled as a tendon spring in series with an isometric force source, or a controllable clutch. To provide the mechanical power for step-to-step gait transitions, a Hill-type soleus muscle is modeled to actively plantar flex the ankle throughout mid to terminal stance using muscle state and force as reflex feedback signals. Finally, to stabilize the trunk during stance, and to protract and retract each leg throughout the swing phase, two mono-articular Hill-type muscles actuate the model's hip joint. State transitions of a finite machine were facilitated by the walking model, and its interactions with a modeled ground surface, and each muscle was engaged or activated according to state [70.54]. Following a forward dynamic optimization procedure described in [70.54], the walking model is shown to predict joint biomechanics, as well as whole-body metabolism, as shown in Fig. 70.8, supporting the idea that the preponderance of leg muscle–tendons operates isometrically, affording the relatively high metabolic walking economy of humans.

70.3.3 Design Principles for Wearable Leg Robotics

Neuromechanical models of human locomotory function such as the *Endo* and *Herr* model [70.54] provide critical insights into wearable robotic leg design. Biophysical models that describe the morphology and neural control of human limbs can motivate robotic designs that are quiet, low mass, economical, and stable;

Fig. 70.7 The musculoskeletal walking model of *Endo* and *Herr* [70.54]. Only three contractile muscles act about the model's ankle and hip joints capable of performing nonconservative positive work, namely the ankle plantar flexor, representing the soleus muscle, and two mono-articular, hip flexor/extensor muscles. All remaining muscle–tendon units of the leg are modeled as an isometric muscle in series with a compliant linear tendon spring. The hip joint also includes a unidirectional, linear torsional spring representing the dominant ligaments that tend to flex that joint

robots that move like, and feel like, their biological counterparts. In the subsequent sections, we discuss key design features critical for a robotic prosthetic, orthotic, or exoskeletal leg to behave like a healthy, normal biological leg. Each design principle is first discussed, and then applied to a leg prosthesis for a transtibial amputee.

70.3.4 Series and Parallel-Elastic Actuation for Power Amplification

Perhaps the most paramount design feature of a wearable robotic leg is a biomimetic actuator architecture designed to achieve biologic levels of powered plantar flexion at the ankle during terminal stance. The biological calf muscles generate nearly 80% of the mechanical work required to complete each gait cycle during mid to late stance plantar flexion, and typically performs greater positive than negative ankle work during each stance period of level-ground walking [70.36, 56–61]. Ankle-powered plantar flexion in the trailing leg is critical for powering the transition from one single support phase to the next single support phase, minimizing impact of the leading leg [70.56, 58]. For this purpose, in the walking model of [70.54] shown in Fig. 70.7, a Hill-type soleus muscle, or ankle plantar flexor, is

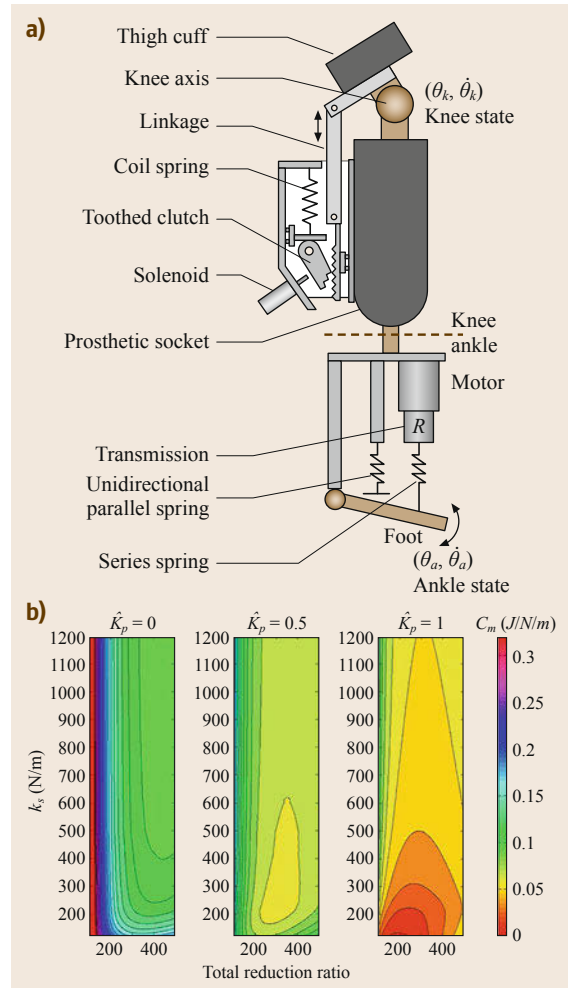

Fig. 70.8 Biomechanical and energetic predictions from the walking model shown in Fig. 70.7. Plotted is the maximum cross-correlation coefficient R , summed across three joint angles and normalized by 3, versus the metabolic cost of transport (COT), or the metabolic energy required to transport unit body weight unit distance. $R = 1$ indicates perfect agreement with biological ankle, knee and hip angle data throughout one gait cycle, whereas $R = 0$ indicates no agreement. Each closed circle is one forward dynamic model solution that can walk for at least 20 s without falling down. The dashed line and shaded area represent mean \pm one standard deviation for human metabolic COT data from the literature [70.55]. The open diamond is the model's optimal solution with a maximal R value, and energetically within one standard deviation of the average human walking metabolism

modeled to actively plantar flex the model's ankle from mid to late stance. The muscle is in series with a tendon spring, representing the Achilles tendon. Further, the

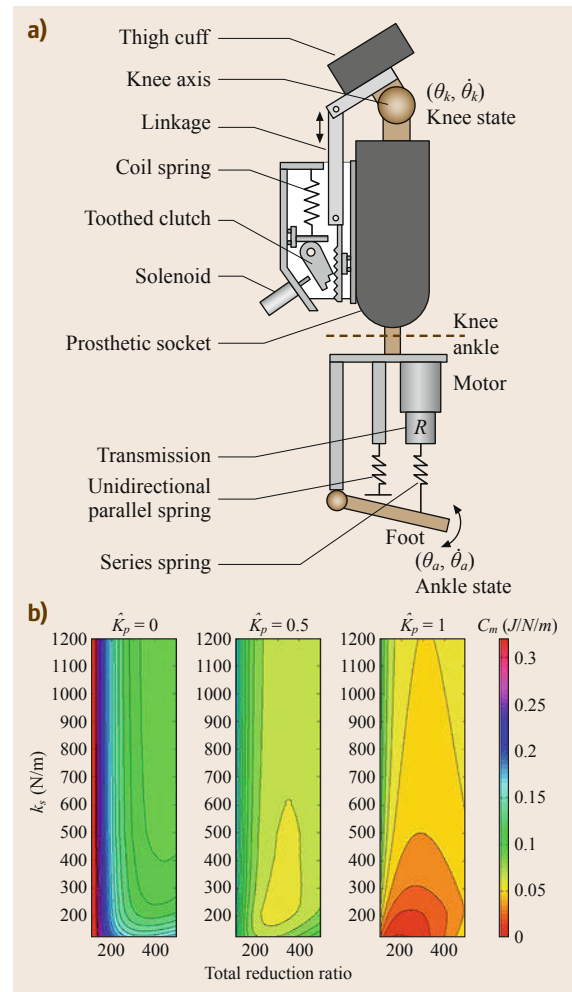

bi-articular gastrocnemius muscle, or the ankle–knee posterior in Fig. 70.7, spanning the ankle and knee, is modeled as an isometric force source, or clutch, in series with a tendon spring.

Such an architecture is critical for powering ankle plantar flexion while still achieving efficient, low-mass robotic actuation. Since the ankle–knee posterior muscle in Fig. 70.7 is shown to transfer little mechanical energy between the knee and ankle throughout the walking gait cycle [70.54], it is reasonable to model this muscle using mono-articular actuators about the knee and ankle. In such a framework, the effect of the ankle–knee posterior on these joints is represented as effective monoarticular torque-producing elements. Such an architecture is shown in Fig. 70.9a showing the schematic of a bionic transtibial prosthesis. Here the ankle is modeled as a series-elastic actuator (SEA) in parallel with a unidirectional parallel spring. The SEA represents the ankle-plantar flexor in Fig. 70.7, and the unidirectional spring represents the torque contribution of the ankle–knee posterior muscle on the ankle joint.

In Fig. 70.9b, the results of a compliant transmission optimization are presented, showing the effects of ankle total reduction ratio, series stiffness, and parallel stiffness on the ankle prosthesis COT. The prosthesis COT is equal to the amount of electrical energy consumed by the prosthesis throughout one gait cycle, divided by the product of half body weight and the distance traveled in one gait cycle. The half body weight in the denominator assumes that each transtibial prosthe-

sis has its own power supply. Without parallel stiffness ($\hat{K}_p = 0$), the energy consumption of the prosthesis is minimal at a total reduction ratio greater than 400, and a series spring stiffness greater than 400 kN m^{-1} . As parallel spring stiffness increases ($\hat{K}_p > 0$), the prosthesis COT can attain a lower minimum value while also requiring a smaller total reduction ratio and series spring stiffness. Using a lower reduction ratio allows the system to have a larger bandwidth, a faster intermittent response, and a lower acoustic noise output. Further, a lower series stiffness improves the prosthesis COT as shown in Fig. 70.9a, shock tolerance upon impact loading at heel-strike [70.62], and motor power amplification at the ankle joint output [70.63]. For further details on compliant ankle transmission design, see [70.62, 63]. In the design of bionic ankle–foot wearable robots, both motor-series and parallel elasticity are of paramount importance.

Fig. 70.9a,b Shown in (a) is a bionic transtibial prosthesis represented as an electromechanical schematic including ankle motor, ankle transmission ratio R , ankle series spring k_s , and ankle unidirectional parallel spring k_p . The parallel spring is unidirectional, engaging only at ankle angles less than 90° but completely disengaged for angles greater than 90° . In addition, spanning the knee joint are elements of a series-elastic clutch mechanism. Plotted in (b) are the results of a compliant ankle transmission optimization showing the effects of ankle reduction ratio, series stiffness k_s and normalized unidirectional parallel stiffness \hat{K}_p on ankle prosthesis cost of transport, C_m . Parallel stiffness, normalized by the human-controlled dorsiflexion stiffness of 630 Nm rad^{-1} is noted as \hat{K}_p on the upper portion of each graph. The total reduction ratio is equal to the SEA moment arm r multiplied by transmission ratio R . The compliant ankle assembly shown in (a) was constrained to track biological ankle torque for a human subject with a mass of 78 kg walking at 1.25 m s^{-1} with a stride distance of 1.4 m . Further details of the compliant transmission optimization can be found in [70.62]. ►

70.3.5 Series-Elastic Actuation for Minimizing Motor Work

It has been hypothesized that the preponderance of leg muscle–tendons generates force at low muscle fascicle speed, allowing economical force generation in level-ground walking [70.54]. In the walking model shown in Fig. 70.7, six of the nine leg muscles act in a purely isometric manner, where a tuned, series-tendon compliance enables full energy absorption and delivery, eliminating muscle work and lowering metabolic demands in walking. Specifically, all muscles spanning the knee, as well as the ankle dorsiflexor, are assumed to act isometrically upon neural activation when ambulating across a level-ground surface.

For wearable robotic actuation in level-ground walking, such behaviors can be achieved using a series-elastic clutch mechanism with a tuned series stiffness. However, for a more diverse set of locomotory tasks such as ascending and descending slopes and steps, the ideal actuator architecture is a series-elastic actuator with a tuned series-spring stiffness where the actuator is designed to lock or clutch at lower power consumption. As an example, for level-ground ambulation using an electric actuator, a clutch acting on the motor shaft can be used to lock the shaft during those times in the gait cycle where a spring response is sought, eliminating the high power consumption required if the motor itself were to clutch the shaft. For other movement tasks outside of level-ground walking, the motor–shaft clutch could then be disengaged, and the motor could apply the necessary torques and impedances required for the task using standard series-elastic actuation strategies [70.64]. Such an architecture allows wearable robotic legs to move economically across level-ground surfaces, while still allowing a great deal of versatility for irregular-ground ambulation, sit-to-stand maneuvers, and general disturbance rejections.

This design principle of using a tuned series stiffness to minimize the need for actuator work has been used in the design of a transtibial prosthesis in [70.65] (Fig. 70.9a). Since the gastrocnemius was modeled in [70.54] as an isometric force source in series with a tendon spring, in the study of [70.65] a series-elastic clutch was mounted at the knee brace to provide the knee flexion action of the gastrocnemius during level-ground walking. The mechanism consisted of a toothed clutch at the free end of a coil spring (spring stiffness of 66 500 N/m) that acted as a knee flexor on a polycentric knee brace. The brace was integrated into a prosthetic socket connected to the ankle–foot prosthesis, as is shown in Fig. 70.9a. When the clutch was engaged via solenoid action, the free end of the spring locked with respect to the socket and the spring stretched as the

knee straightened. The force developed by the spring produced a flexion torque at the knee joint. Conversely, when the clutch disengaged no torque was applied at the knee joint. The spring acted on the knee joint with a moment arm that varied between 0.02 and 0.03 m as a function of knee angle. This moment-arm function was designed so that the apparent knee stiffness matched that of the biological knee during level-ground walking [70.66].

70.3.6 Neuromuscular-Based Reflexive Control

We present a sensing and control scheme for producing biomimetic positions, torques and impedances at the hip, knee, and ankle joints of a powered leg prosthesis, orthosis, or exoskeleton during walking and running gaits. In this paradigm, sensory data are collected using intrinsic and/or extrinsic sensors. Here intrinsic sensing refers to information collected from sensors located on the wearable robotic device, and extrinsic sensing refers to all information collected from sensors located externally to the wearable device. As an example, in the case of a leg prosthesis, a surface electrode for the measurement of the electromyographic signal from residual limb muscles would be an extrinsic sensor, and an inertial measurement unit located on the device itself would be classified as an intrinsic sensor. Intrinsic sensors measure device positions, motions, forces, torques, pressures, and temperatures, whereas extrinsic sensors might comprise such mechanical and temperature sensors positioned external to the wearable device, as well as neural sensors for the determination of user motor intent.

In the neuromuscular-based control framework, such sensory data are passed to a neuromuscular model of human locomotion, such as the *Endo* and *Herr* model [70.54] presented in Fig. 70.7, which is used to compute appropriate joint dynamics for the device to provide to the user. The model-based control scheme, depicted in Fig. 70.10, relies on data collected from both intrinsic and extrinsic mechanical sensors, and extrinsic neural sensors used to infer the motor intent of the user, volitionally and/or nonvolitionally. The neuromuscular model used to compute desired joint dynamics may include muscles modeled in a variety of ways. These muscle models (muscle model block in Fig. 70.10) may include, for example, a bilinear muscle model or a Hill-type muscle model [70.67]. The measured states of the robotic joints are used to determine the internal state (length, velocity) of each of the virtual muscle–tendon units of the neuromuscular model using morphological information of the muscle moment arms about each modeled joint. This geometrical transforma-

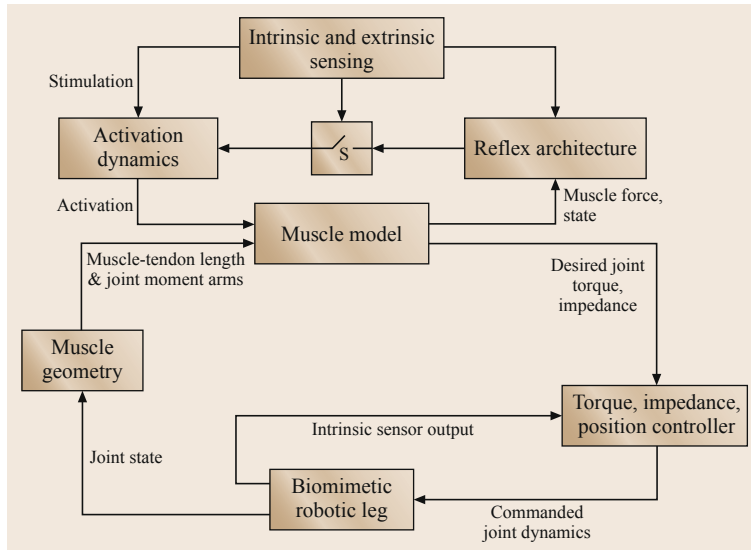

Fig. 70.10 Block diagram of a neuromuscular model-based control architecture for a bionic wearable robotic leg

tion occurs within the muscle geometry block shown in Fig. 70.10.

The impedance and force of each virtual muscle are additionally governed by the muscle activation, which may be determined from a local reflex loop, an external source, or a combination thereof. In the reflex case, a feedback loop is implemented where virtual muscle force and state are used to produce muscle stimulation, which is then filtered to produce muscle activation (activation dynamics block in Fig. 70.10). This feedback-based control scheme is designed to emulate the force feedback and stretch reflex of an intact human muscle. This reflexive feedback loop can be a linear or nonlinear function of virtual muscle force, length, and velocity. For example, the reflexive feedback loop can be nonlinear, comprising a threshold prestim parameter, as well as force and state gains and exponents, or

$$u(t) = x + y_F [F(t - \Delta t_F)]^{z_F} + y_l [l(t - \Delta t_l)]^{z_l} + y_v [v(t - \Delta t_v)]^{z_v}, \quad (70.1)$$

where x is the prestim parameter, y_i are force and state gains, z_i are force and state exponents, and t_i are corresponding delays.

In the case where muscle activation is determined solely by an external source, a neural sensor might be used to provide some estimate of motor intent, which is then input to the activation dynamics block where a muscle activation is estimated as an input to the muscle model. Typically, such measurements of motor intent would comprise one or more peripheral neural sensors from implants interfacing with nerves and/or

muscles, but in the most general case, such motor intent commands may additionally be measured from central brain implants.

In the combination case, the framework of Fig. 70.10 describes a procedure where the reflexive parameters are modulated by the controller either within a single gait cycle, and/or from gait cycle to gait cycle in an updating manner, based upon detected variations in gait speed and terrain. Extrinsic efferent neural signals from muscles and/or peripheral nerves might be used to modulate reflexive parameters, such as force and state gains and exponents. For example, measured calf muscle EMG in a transtibial amputee has been used to modulate the gain of a positive torque feedback during the stance period of a walking gait cycle, providing the amputee direct volitional control over powered plantar flexion during terminal stance in walking [70.68]. Clearly, one day it may be possible to stimulate through a nerve implant to reflect intrinsic/extrinsic mechanical sensory data as an afferent feedback signal to allow the user of the wearable robot to better modulate efferent neural motor commands for a desired wearable robotic dynamical response.

Once the force of each virtual muscle spanning a joint is determined (using the implemented muscle model), each muscle force is multiplied by its biologically realistic muscle moment arm and then all muscle torque contributions are summed around the joint to produce a net torque and impedance estimate. The model estimates are then sent to the controller (Fig. 70.10) as the desired net torque and impedance for each robotic joint. The controller tracks these desired values at each joint to produce human-like joint forces and impedances. In the case where the human

user's motor intent is to control device joint position, the controller would integrate the desired joint torque to achieve a joint position estimate, and then modulate device joint position to achieve that desired position.

By way of example, we present a neuromuscular-based control of a transtibial prosthesis (Fig. 70.11). For this example, the model-based control framework of Fig. 70.10 is used to control the prosthetic apparatus. In the study of [70.65], ankle and knee joint states of the apparatus were measured and used to provide real-time input to a neuromuscular model simulated by an on-board microcontroller. The resulting torque command from the neuromuscular model was used to produce ankle torque while a knee controller adjusted the torque produced by the knee brace. This configuration, shown in Fig. 70.11, was set up to enable the prosthetic apparatus to behave as if it were a human lower leg with reflex-controlled muscles acting at the ankle (Fig. 70.12).

70.3.7 Leg Exoskeletons

Research has lead to the development of leg exoskeletons with the prime intention to allow otherwise healthy individuals to perform difficult tasks more easily or

enable them to perform tasks that are otherwise impossible using purely human strength or skill [70.69]. Early developments in leg exoskeletons consisted of long bow/leaf springs operating in parallel to the legs and were intended to augment running and jumping [70.70]. Each leg spring was engaged during the foot contact to effectively transfer the body's weight to the ground and to reduce the forces borne by the stance leg. During the aerial phase, the parallel leg spring was designed to disengage in order to allow the biological leg to freely flex and to enable the foot to clear the ground. In 1963, Zarodny published a technical report detailing his work on a *powered orthopedic supplement* intended to augment the load-carrying abilities of an able-bodied wearer such as a soldier [70.71]. Other early implementations of exoskeletons, including legs, were attempted by General Electric Research with the *Hardiman* project [70.72], by Moore at the Los Alamos National Laboratory, and *Rosheim* [70.73]. However, a major impetus for the recent work in performance augmenting exoskeletons has come from the **DARPA** (Defense Advanced Research Projects Agency) program *Exoskeletons for Human Performance Augmentation (EHPA)* [70.74], the outcomes of which were different working exoskeletons.

Fig. 70.11 Labeled schematic and control architecture for the prosthetic apparatus. Rotary elements in the ankle-foot prosthesis are shown as linear equivalents in the model schematic to improve clarity. In the control schematic, the parallel spring contribution to prosthesis ankle torque, τ_p , was subtracted from the desired ankle torque command from the neuromuscular model, τ_d , to obtain the desired SEA torque, $\tau_{d,SEA}$. A motor current command i_{mot} was obtained by dividing the desired SEA torque by the motor torque constant, K_t . The knee clutch was engaged via the solenoid depending on knee state as obtained from the knee potentiometer. For further details on the mechatronic and control design, see [70.65]

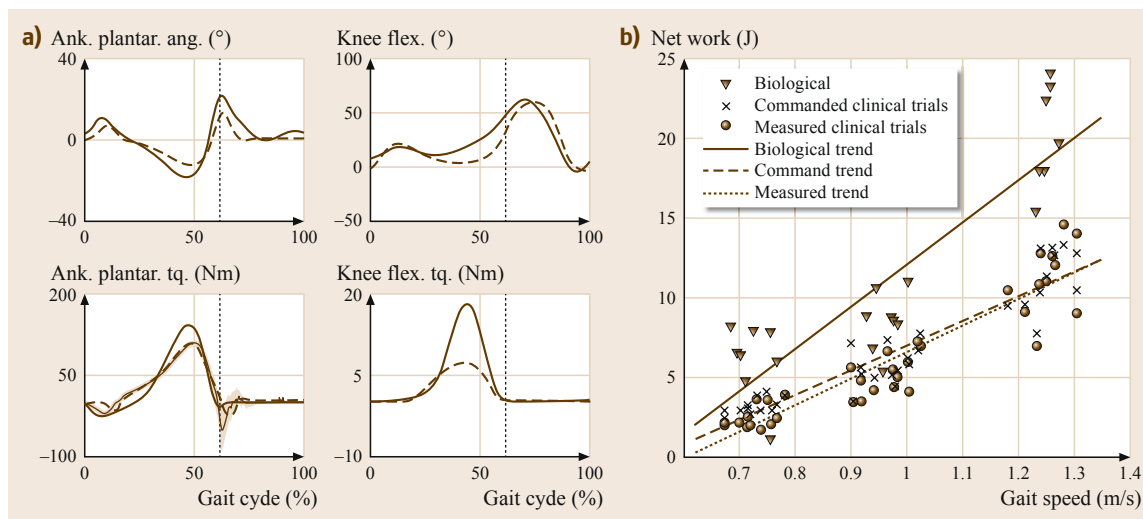

Fig. 70.12 (a) Comparison of prosthesis ankle and knee angles and torques during the clinical trials (measured) with those from a height- and weight-matched subject with intact limbs (biological). The biological values are the thick solid lines (with shaded errors) in each plot while the dashed lines are the values measured on the prosthesis. In the ankle torque plot the commanded torque is shown as a thinner solid line, again with shaded error bars. The knee torque plot compares the torque provided by the clutch-spring mechanism to that provided by the natural gastrocnemius in simulation. The vertical line indicates toe-off in each plot. **(b)** Energy output of the ankle across gait speed. Shown are biological data, net work as commanded by the ankle-foot prosthesis during clinical trials, and measured net work during the clinical trials. For further details on experimental methodology and results, see [70.65]

In this framework, the Berkely Exoskeleton (BLEEX) was the first example of an energetically autonomous system [70.75]. BLEEX features 3-DOF at the hip, 1 at the knee, and 3 at the ankle. Of these, four are actuated: hip flexion/extension, hip abduction/adduction, knee flexion/extension, and ankle inversion/eversion. Of the unactuated joints, the ankle inversion/eversion and hip rotation joints are spring loaded, and the ankle rotation joint is free-spinning [70.76]. The BLEEX exoskeleton [70.77] was designed with linear hydraulic actuators since they were the *smallest actuation option available* based on their *high specific power (ratio of actuator power to actuator weight)* [70.78, 79]. However, a further study determined that electric motor actuation significantly decreased power consumption during level walking in comparison to hydraulic actuators [70.80, 81]. The weight of the implementation of the electrically actuated joint, however, was approximately twice that of their hydraulically actuated joint (4.1 versus 2.1 kg). Significant effort was made in developing a hybrid hydraulic-electric portable power supply [70.82]. In terms of performance, users wearing BLEEX can reportedly support a load of up to 75 kg while walking at 0.9 m/s and can walk at speeds of up to 1.3 m/s without the load. A second generation of the Berkeley exoskeleton is currently in testing. A laboratory spin-off company called Berkeley Bion-

ics (Berkeley, CA) has been created in order to market exoskeleton technology.

A quasi-passive exoskeleton concept has been advanced in the Biomechanics Group at the Massachusetts Institute of Technology (MIT) Media Laboratory that seeks to exploit the passive dynamics of human walking in order to create lighter and more efficient exoskeleton devices. The MIT exoskeleton employs a quasi-passive design that does not use any actuators for adding power at the joints. Instead, the design relies completely on the controlled release of energy stored in springs during the (negative power) phases of the walking gait [70.83]. The 3-DOF hip employs a spring loaded joint in the flexion/extension direction that stores energy during extension that is released during flexion. The hip abduction/adduction direction is also spring loaded, but only to counter the moment induced by the backpack load. Additionally, a cam mechanism was incorporated into the hip to compensate for the relative change in length between the thigh of the exoskeleton and the user due to the joint offset during abduction/adduction. Additionally, spring loaded hip rotation and ankle rotation joints were included to allow nonsagittal plane limb movements. The knee of the MIT exoskeleton consists of a magneto-rheological variable damper that is controlled to dissipate energy at appropriate levels throughout the gait cycle. For the

Fig. 70.13 MIT exoskeleton during metabolic testing

ankle, separate springs for dorsi and plantar flexion are implemented in order to capture different behaviors during these two stages of motion, and store/release the optimum amount of energy. Without a payload, the exoskeleton weighs 11.7 kg and requires only 2 W of electrical power during loaded walking. This power is used mainly to control the variable damper at the knee. The first studies on the metabolic cost associated with walking under the aid of an exoskeleton have been reported by using the MIT exoskeleton [70.84] (Fig. 70.13).

Further experimental work with the MIT quasi-passive exoskeleton showed a significant reduction in metabolic cost of walking versus the same exoskeleton without the springs at the hip and ankle and the variable damper at the knee, demonstrating the utility of quasi-passive elements.

Other examples of leg exoskeletons comprehend the hybrid assistive leg developed at the University of Tsukuba by Sankai [70.85] that is targeted for both performance-augmenting and rehabilitative purposes. At the Kanagawa Institute of Technology in Japan, researchers have developed an exoskeleton for the purpose of assisting nurses during patient transfer [70.86]. Yobotics, Inc. (Cincinnati, OH) [70.87] developed a simple exoskeleton for adding power at the knee to assist in stair climbing and squatting during load-carrying tasks [70.78]. Researchers in the Departments of Mechanical Engineering and Physical Therapy at the University of Delaware have developed a passive leg orthosis that is designed to reduce the forces of gravity on the patient during walking, thus easing the effort required for locomotion [70.88]. Caldwell has developed a 10-DOF lower limb exoskeleton device [70.81]: actuation is provided to the flexion/extension directions of the hip, knee, and ankle, and abduction/adduction of the hip via pneumatic muscle actuators. Recently, few leg exoskeleton systems have been commercialized worldwide by different companies: the ReWalk lower limb exoskeleton developed by Argo Medical Technologies, Israel [70.89] for elderly/paraplegic assistance, and the system called REX developed by Rex Bionics, New Zealand [70.90].

70.4 Whole Body Wearable Systems

Despite the considerable interest and impressive advancements in the field, so far only few researchers have attempted the development of full-body EHPA (FB-EHPA), in particular fully actuated systems for heavy-duty applications, and the available scientific literature is quite limited [70.8, 83, 85, 91–99]. This section reviews the general design issues concerning electro-mechanical design of FB-EHPA. The general design issues are analyzed considering and presenting a series of specific designs.

70.4.1 General Issues

Kinematic Architecture

The kinematic scheme of FB-EHPA is a fundamental aspect that strongly affects the basic functionalities and capabilities of such machines. Just as other wearable

robots, the kinematic design is strongly influenced by the close proximity of robot linkages and human limbs. Kinematics of an FB-EHPA must be designed in order to be compatible with:

- The execution of common human movements: walking, squatting, lifting, turning, etc.
- Requirements for the execution of specific tasks: raising weights, handling specifically shaped objects, running, etc.
- Encumbrance and spatial limitation
- Possible collisions with the operator body and self-interferences.

Common solutions for the existing FB-EHPA are based on anthropomorphic kinematics since this kind of solution guarantees:

- The best workspace matching with reduced encumbrances
- The most simple strategy to avoid self/body collisions
- The execution of common human movements
- Mass distribution that is compatible with human executed tasks.

A full anthropomorphic design that allows replicating all the human **DOFs** could be desirable; however, the complexity of such a system would be far above what is technically affordable. In this sense, a drastic simplification is required to reduce complexity without affecting the basic functional requirements of the machine. This type of simplification is assumed in many of the available **FB-EHPA**.

70.4.2 Specific Design

According to a historical perspective, the first technical concepts of **FB-EHPA** were proposed in 1956 by *Lent*, who proposed an inflatable space suit with powered joints to assist the wearer during the flexion of suit extremities stiffened by the internal pressure [70.92]. Lately, in 1966, *Mizen* proposed, although without realizing it, the first man amplifier for civilian and military applications [70.93].

The first practical investigation was instead attempted by General Electric between 1965 and 1971, by developing the Hardiman [70.94] that is briefly described in the following section. Researches on **FB-EHPA** were resumed in 1996, when *Snyder* and *Kazerooni* proposed a novel under-actuated material handling system with 6 passive joints (2 for the legs and 4 for the arms) and 12 electrically actuated joints (6 for the legs and 6 for the arms) under force-feedback control [70.95]. System arms and legs were implemented and tested separately.

Following this renewed interest, from 2002 to 2009, three different under-actuated **FB-EHPA** have been developed in Japan for medium-duty applications, such as nursing care [70.83, 97], disabled or elderly assistance [70.85], and agriculture [70.100]. The best performing and most renowned system is the hybrid assistive limb (**HAL**) [70.85]. Still in Japan, in 2009, Panasonic-Activelink presented the POWER LOADER, a heavy-duty **FB-EHPA** for material handling [70.98]. In 2010, Raytheon-Sarcos unveiled the XOS2 [70.99, 101], which is one of the most advanced and performing medium-duty hydraulically actuated **FB-EHPA** for military/logistics applications. One of the latest **FB-EHPA** is called Body Extender (**BE**) [70.102] and has been realized at the PERCRO Laboratory,

Scuola Superiore Sant'Anna (Italy). The **BE** is a full electrical machine developed for heavyweight material handling. In 2012, the French company RB3D has presented **HERCULE**, an electrically actuated **FB-EHPA** with legs similar to those of **HAL**, but with different arm kinematics, and designed for lifting 20 kg with each arm at full horizontal extension. **HERCULE** has been developed for the French Ministry of Defense and detailed specifications are not available at present.

In this section, an overview of the basic features of some of the most relevant and advanced existing systems is provided.

Hardiman

Hardiman I is the first prototype of **FB-EHPA** and has been developed between 1965 and 1971 by General Electric Research (Schenectady, NY). The project aimed at developing a high-power machine for handling heavyweight materials in unstructured environments. The project was jointly supported by Engineering Psychology Programs-ONR, Naval Air Systems Command, and the Army Mobility Equipment Research and Development Center (Fort Belvoir).

The project results have been reported by *Fick* and *Makinson* in [70.94]. Hardiman I has a structure based on a 30-**DOF** kinematics including:

- 2-**DOF** for each end-effectors: two flexion movements of a two-phalanges finger
- 7-**DOF** for each arm: wrist flexion, forearm rotation, elbow, upper arm rotation, shoulder flexion, back flexion and arm abduction/adduction
- 4-**DOF** for each leg: hip abduction/adduction, hip flexion, knee flexion and ankle flexion
- 2-**DOF** for each foot: ankle inversion and ankle rotation.

The actuation system employs hydraulic actuators that require an external hydraulic circuit at 206 bar (3000 psi) with a power of 18.6 kW (25 hp). The global weight of the system is 680 kg (1500 lbs) and the exoskeleton is rated for a lift capability of 6800 N (1500 lbs). The control of the hand is completely hydromechanical (implemented with no electronic components), while the arms, legs, and feet are controlled through electrohydraulic systems. Hardiman I did not succeed to be tested in its full functionalities. In particular, the developers reported several problems in the implementation of the controller for the lower limbs, mainly also due to the lack of reliable electronic components and reduced computation power characterizing the technology at that time.

Fig.70.14a,b Picture of the Body Extender (BE): (a) system worn by a user; (b) rear view (after [70.103])

HAL: Hybrid Assistive Limb

HAL is a series of full-body exoskeleton systems, the development started in 1996 and the current version, **HAL-5**, is the first commercial version. **HAL** has been developed by *Sankai* [70.85] and his research group of the University of Tsukuba and commercialized by the company Cyberdyne, Inc. (Tsukuba, Japan) [70.103].

It is realized in two versions, the first one is for lower limbs only and the second includes the upper limbs. The exoskeleton is developed with the aim to expand, augment, and support human physical capability in the field of medical welfare, heavy work support, and entertainment. The kinematic structure features 6 passive joints (2 for the legs and 4 for the arms) and 8 electrically actuated joints (6 for the legs and 6 for the arms). **HAL** is commanded via a specially designed controller which takes into account the wearer's muscular activity through the employment of bioelectrical signals from **EMG** sensors that are disposed on wearer's skin. **HAL** weighs 23 kg in the full-body version, including batteries for an autonomy of 2 h and 40 min. Although the lifting capabilities are not specified, it is reported in [70.97] that laboratory tests have been conducted with a payload of 15 kg with each arm at full horizontal extension; however, it requires locking of the passive joints and an additional wrist support. **HAL** is currently being experimentally tested in clinics and the research group is currently working on improving the system with new control algorithms.

POWER LOADER

POWER LOADER is a full-body exoskeleton developed by Activelink Ltd, a spin-off of Panasonic Ltd, Japan. The system development was started in 2003 and the first working prototype reported in literature has been realized in 2010. **POWER LOADER** has been

developed for rescue operation in natural disaster scenarios such as big earthquakes. The mechanical design is based on an anthropomorphic design only for the arms. The legs have an anthropomorphic structure. The knee is back rotated [70.98] in order to leave more free space around the user legs. The actuation is achieved through electric motors and drivers.

PERCRO Body Extender

One of the latest full-body exoskeleton has been realized at the PERCRO Laboratory of Scuola Superiore Sant'Anna, Italy (Fig. 70.14). The developed **FB-EHPA** has been named as the body extender (**BE**) [70.104]. The **BE** comprises two identical legs with 6-DOF each, whose kinematics is isomorphic to the wearer's kinematics, and two identical arms with 5-DOF each. All 22-DOF are powered by modular highly efficient actuation units; this solution allows to reduce the power consumption, as well as to minimize the costs and efforts related to its production and maintenance. The **BE** weighs 160 kg, can provide a maximum continuous usable power of 16.5 kW, is capable of lifting 50 kg with each arm at full horizontal extension, and is designed for transporting loads up to 100 kg at a walking speed of 0.5 m/s. Potential application of this system is in earthquake disaster relief operations, where search and rescue teams need to walk across tight spaces over debris and to remove rubble in an attempt to find, release, and transport survivors. The system has been integrated and fully tested in 2010 and it is currently being improved in terms of energy efficiency and stability on uneven terrains.

Commercial Systems (Uncovered by Scientific Literature)

In the past years, two advanced commercial systems have been unveiled. The first one is **XOS II**, which is the second version of a full-body exoskeleton developed by a US company, Sarcos-Raytheon [70.99, 101, 105]. The first version of the system was completed in 2008 and the second version has been presented in 2010. The **XOS II** has been developed aiming at logistic applications in the military field. It is based on an anthropomorphic kinematics equipped with 24-DOF actuated with hydraulic systems. It weighs 95 kg and has a lifting capability of 230 N. The company is currently working on improving the energy efficiency for the realization of an autonomous (untethered) version of the system. The second device is called **HERCULES** and has been presented in 2012 by RB3D (France). It is an electric-driven system that has a lot of similarities with the **HAL-5** exoskeleton. The details of **HERCULES** have not yet been disclosed [70.106].

70.5 Control of Human–Robot Augmentation Systems

From a control point of view, the functionality of a power augmentation system should simultaneously provide (a) force amplification and (b) support to natural locomotion.

Hence, the control of exoskeleton for human power augmentation (EHPA) can be split into two major sub-systems: lower- and upper-body designs. The first sub-system cooperates with a human gait, while sustaining much of the body loads, keeping overall equilibrium and following the human motion with transparent and natural reflection forces. The second subsystem enhances human manipulation abilities through the multiplication of the arm forces during grasping operations of heavy loads.

Both components have to respect the following requisites:

1. *Stability*: The stability margin of the (linearized) control system should be large enough to cope with the environment and operator uncertainties, and to avoid uncompensated oscillations entering into resonance with the human postural control.

2. *Transparency*: The system should be highly reversible (through mechanical design or sensor augmentation) in order to allow a correct perception of the overall interaction with the environment and the proper generation of the control actions.
3. *Regular force amplification*: The gain ratio of the human force amplification should be kept as regular as possible in all interaction conditions, including a large bandwidth of interaction, different postures, and different environment interactions.
4. *Fast response*: The bandwidth and the saturation values of the position/velocity/force controllers should be as close as possible to their respective ranges used in natural motions and interaction.

70.5.1 A Historical Perspective

Yagn [70.70], first submitted a series of patents for facilitating human walking and running. At that time, the mechanism was limited to a series of springs and clutches, which altered the feet compliance during walking and used the potential energy of the springs to have a more efficient walk.

The use of active orthoses, through hydraulic servo-valves was proposed by Filippi in 1937 [70.107]. The proposed system was a knee orthosis whose motion in the sagittal plane is powered by a hydraulic piston. At that time, there was not much advancement on electric control of hydraulic systems and the joint control was supposed being regulated mechanically. A crank located on the hip moved a cam that, on its own, wound a torsional spring on the knee. The other extremity of the spring was used to regulate the piston flux.

The first documented attempt to develop a powered suit that amplifies human force was performed by Clark et al. in the early 1960s [70.39]. At that time, they proposed to design a man amplifier using hydraulic amplification. In Fig. 70.15, it is represented by the device interaction model and the basic control loop they proposed. They have limited the investigation to one single joint of movement.

In Clark et al.'s work, each joint was regulated with an independent position controller that was actuated by mechanical pistons placed closed to the human body. The control was based on an admittance scheme that translates user commands into joint velocities. This scheme had no opportunity to show the reflection of contact forces.

The design and control of whole-body active exoskeletons started in 1965 with a joint Naval Army program who supported General Electric for the design of a whole-body EHPA (Hardiman I). The power

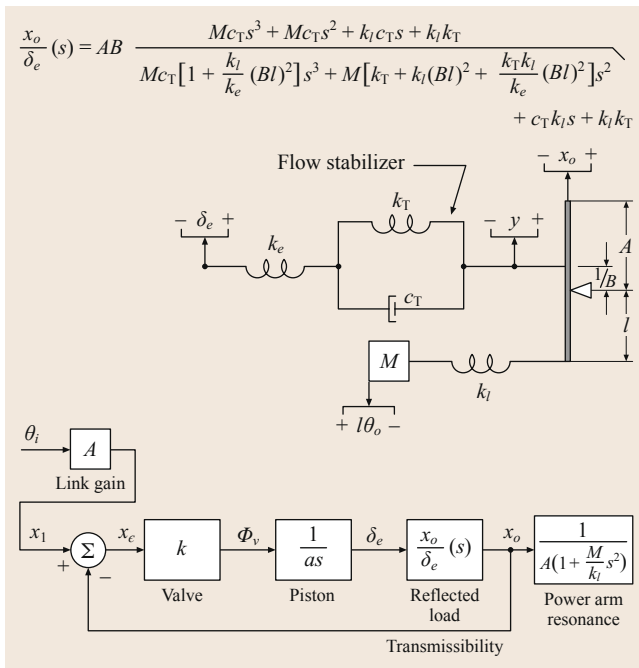

Fig. 70.15 The control of the force amplifier joint (after [70.39]). The upper scheme represents the mechanical equivalent circuit for the control of the elbow joint, and the above equation represents the associated force balance equation. The lower scheme is a block diagram that represents how the components are arranged together and how the feedback is used to control the joint actuation

augmentation target was fixed to an amplification factor (robot versus human) 25 : 1 having a nominal total force about 10 000 N.

The proposed device had 28 independent DOFs plus two grasping tools with one additional DOF each.

The control concept design of Hardiman was very ambitious. In the first attempt, the designer developed a set of mechanical servo-valves (as shown for the *master hand controller* in Fig. 70.16) placed in contact with the user's skin which responded to local pressure by deflecting the flux of hydraulic circuits [70.96].

The approach worked well only for simplified kinematics of the mechanical hand, while the dynamic interference between the serial kinematics of the arm link required the use of electrohydraulic circuits and that of a computer-developed dynamical model.

The project development stopped due to major limitations in the design and control of the lower leg. During the development, the authors only have tried unilateral electrohydraulic servos to track the motion of the user legs. The major development issue was related to the control of the leg for the body balance. The developers devised that the leg functionality changes between the stancing and the swinging phase, but the use of switches to detect the current leg phase demonstrated to be ineffective to validly cope with equilibrium and stability issues. Other issues were instead related to the power supply line (45 kW needed by the prototype) and to the kinematics differences between the master and the slave arm, which makes some motion unnatural, risky, and sometimes unstable for the driving user.

Few years later, Vukobratovic et al. [70.108] started to develop an exoskeleton to assist injured people (mostly paraplegic) to recover basic walking abilities. That work shares several features that are being imple-

mented in present power extenders. Vukobratovic et al. were able to define the following relevant features of control and stabilization loops for walking that are still valid today:

- A model reduction approach
- The method of prescribed synergies
- The use of zero moment point (ZMP) to derive the dynamic equation of motion
- The use of left–right symmetries and nominal gait cycle
- The design of a *model-based* analog motion compensator that provides to create motion synergies through a set of servomotors.

Motion synergies were computed using a nominal gait trajectory (step period = 1, step size coefficient = 1) in a reduced phase space as a reference to derive in advance the weight, the inertia, and the friction compensation torques that have to be exerted at each joint.

Figure 70.17 describes the high-level functional architecture of the controller. The adaptation for different gait conditions (from 1 to 5 s) was modulated on the precomputed trajectories through a couple of coordinated sequencers (time-base generators, TBG) that convert the absolute time into the loop phase required to determine compensation components.

The overall feedback also includes two additional feedback components, which use force sensors in the shoes to compute torque perturbation around the ZMP. These disturbances appear when the exoskeleton rotates around the leg in the stance phase or when a change of acceleration (step length/period) alters the gait from the nominal cycle.

In both cases, the author derived, through linearization of the dynamic model along the nominal cycle, a couple of static gains that map the sense forces into corrective torques that are added to the nominal hip torques.

Vukobratovic et al.'s exoskeleton worked well only for limit cycles which were close to the nominal gait trajectory it was designed for. Both Vukobratovic's exoskeleton and the experience derived from the Hardiman project showed that the control technology available at that time was premature to cope with the nonlinear, dynamic coupling effects that appears in walking and manipulation.

A renewed effort in research was performed by researchers at Berkeley University who in the middle of the 1980s promoted projects, in general called the *human extenders*, to develop arm exoskeletons that augment the arm force. Early extender projects were

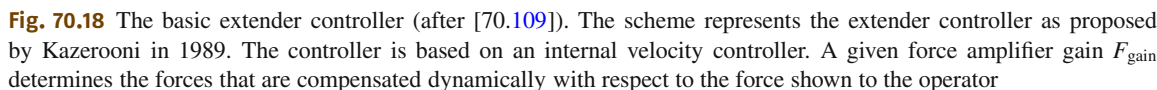

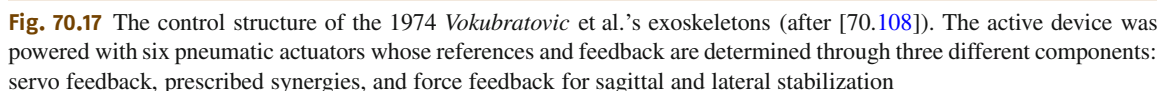

Fig. 70.16 The master hand controllers. A set of *tinklers* were moved according the grasping force of the user and drive the hydraulic circuit of the slave hand with a design amplification factor of 25:1 (after [70.96])

of the nonlinear model interacting with the unstructured environment. However, the stability conditions derived in [70.2] through the small gain theorem were highly restrictive and required the amplification gain to be less than 1. Subsequent author's work introduced different criteria (than fully unstructured interaction), such as typical operator and environment impedance ranges, and stability margins. Under such conditions [70.110] and using the μ -synthesis, the author demonstrated robust stability under higher force amplification gains.

An example of the amplification goal achievement with this technique and a 3 DOF arm was reported

in [70.111] as the maneuver bandwidth of 2 Hz, the vertical force amplification ratio 7 : 1, and the horizontal force amplification ratio 5 : 1.

70.5.2 Power Augmentation through Proprioceptive Sensors

This type of power augmentation systems use only sensors that are completely internal to the exoskeleton structures. These sensors have no direct contact with the human operator (e.g., motor or joint torque/position sensors).

One benefit of this approach is the reduced design complexity through the use of more conventional torque sensors and the improved stability of the reading even in the case of multiple contacts between the user and the exoskeleton structure.

As a side effect, there is no direct measurement of the force effectively felt by the user. The interaction controller decides the exoskeleton motion policy based on the estimation of the interaction force with the user.

This approach is used in the control of the Berkeley Lower Extremity Exoskeleton [70.5], and most of the intelligent assisting devices (IADs) [70.112–114].

Given the Lagrange formulation of the exoskeleton, the basic of this approach is to let the control providing a predefined percentage of the force/torque required for the motion

$$\begin{cases} \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{G}(\mathbf{q}) + \mathbf{G}_L(\mathbf{q}) = \\ \quad \mathbf{Q} + \sum_c \mathbf{J}_c \mathbf{F}_c, \\ \mathbf{Q} = \mathbf{J}_t^T(\theta) \mathbf{F}_m, \\ \dot{\mathbf{q}} = \mathbf{J}_t(\theta) \dot{\theta}, \end{cases} \quad (70.2)$$

where \mathbf{q} is the joint coordinates vector, \mathbf{M} , \mathbf{C} , and \mathbf{G} , are the exoskeleton mass, Coriolis, and gravity matrices, respectively, \mathbf{G}_L is the manipulated load, \mathbf{Q} is the motor-torques vector reduced to the joints \mathbf{J}_c , \mathbf{F}_c refers to the user contact forces and the respective Jacobians computed in the points of contact, and \mathbf{J}_t and \mathbf{F}_m represent the transmission Jacobian and the motor force/torque vector, respectively, and θ is the motor-coordinates vector.

In order to properly work, this approach also supposes to have an almost accurate model of the mechanical design ($\hat{\mathbf{M}}$, $\hat{\mathbf{C}}$, $\hat{\mathbf{G}}$, $\hat{\mathbf{J}}_c$, $\hat{\mathbf{J}}_t$) and the load to manipulate ($\hat{\mathbf{G}}_L$). In these conditions, the candidate control law is

$$\begin{aligned} \mathbf{F}_m = & (\mathbf{J}_t^T)^{-1}(\hat{\mathbf{G}}(\mathbf{q}) + (1 - \beta^{-1})\hat{\mathbf{G}}_L \\ & + (1 - \alpha^{-1})(\hat{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}})) . \end{aligned} \quad (70.3)$$

By inserting (70.4) in (70.2), we have

$$\begin{cases} \alpha^{-1}(\hat{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}} + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}) + \beta^{-1}\mathbf{G}_L(\mathbf{q}) \\ = \sum_c \mathbf{J}_c \mathbf{F}_c + \varepsilon(\mathbf{q}) \\ \varepsilon(\mathbf{q}) = (\mathbf{M}(\mathbf{q}) - \hat{\mathbf{M}}(\mathbf{q}))\ddot{\mathbf{q}} + (\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) \\ - \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}))\dot{\mathbf{q}} + (\mathbf{G}(\mathbf{q}) - \hat{\mathbf{G}}(\mathbf{q})) \\ + (\mathbf{G}_L(\mathbf{q}) - \hat{\mathbf{G}}_L(\mathbf{q})), \end{cases} \quad (70.4)$$

where the model error is expected to converge toward zero.

Equation (70.4) shows how the contact forces perceived by the user can be reduced by a static (β) and/or a dynamic (α) amplification factor. As a matter of fact, if the simplification operates correctly ($\varepsilon \rightarrow 0$), the pilot will only feel on his own body a percentage of the carried load (β^{-1}) plus a percentage of the exoskeleton dynamic (α^{-1}).

In the case of a walking exoskeleton, the above control model is switched according to the stancing foot, or in the case of double stancing (the weight is distributed on both feet), a simplified zero-moment-point (ZMP) rule is applied [70.115]

$$\begin{cases} m_{\text{TR}}x_{\text{TR}} = m_{\text{TL}}x_{\text{TL}}, \\ m_{\text{TR}} + m_{\text{TL}} = m_L, \\ \frac{x_{\text{TR}} + x_{\text{TL}}}{2} = x_g, \end{cases} \quad (70.5)$$

where x_{TR} and x_{TL} are the stancing position of the right and left feet, respectively, x_g is the projection of the center of mass on the walking plane, m_L is the overall load mass, and m_{TR} and m_{TL} are the mass components to be distributed on the right and left control models, respectively.

Equation (70.5) is used as a means to separate the closed-loop kinematics into two (quasi) symmetrical equations, similar to (70.2), that only refer to the left- and right-leg dynamics. The load is consequently distributed among the two legs, thus generating two *de-coupled* control models, one for each leg.

Discussion 70.1

Experiments on such a kind of controller were performed at UC Berkeley. In [70.75], the system proved to be efficient to compensate completely the weight ($\beta^{-1} = 0$) with a good dynamic scale power amplification factor ($\alpha = 10$), and that the resulting system is usable for walking at an average speed of 1.3 m/s with a transported payload of 70 kg (including the exoskeleton weight).

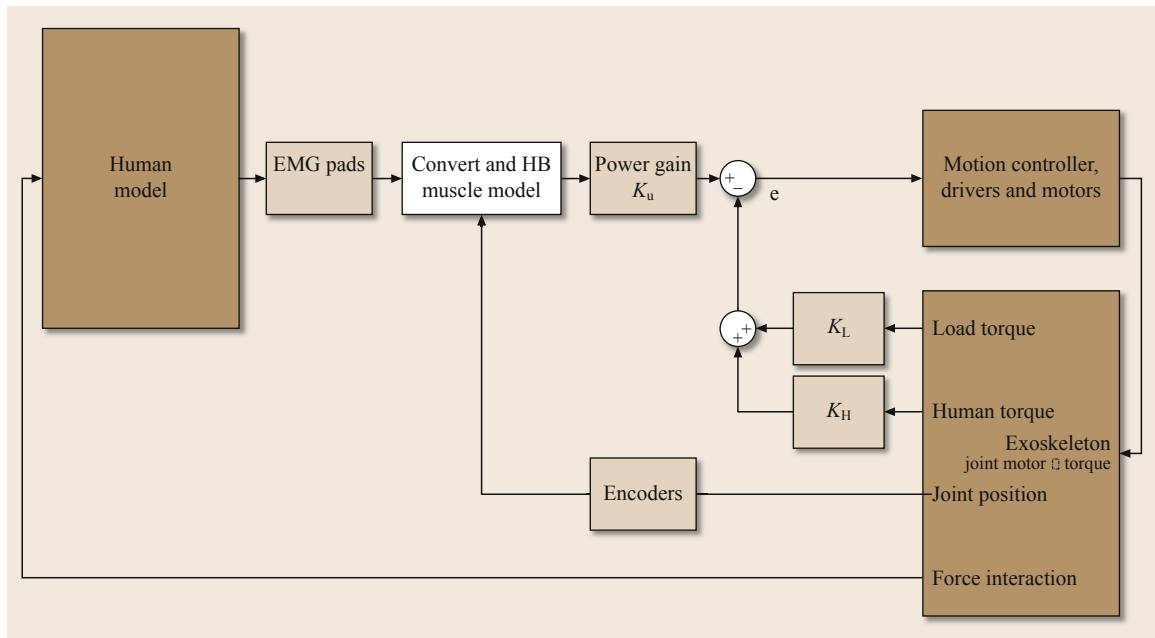

Fig. 70.19 The basic EMG controller (after [70.116]). The myo-electric signals were processed to derive a control signal through a sequence of (1) high-pass filter; (2) signal rectification (absolute value); (3) low-pass filtering; (4) normalization versus a nominal setup isometric contraction. The sign of the contraction is detected as a combination of pure agonistic–antagonistic contractions

The proposed design, however, suffers from a number of drawbacks that limit this control architecture being used in a more flexible interaction environment:

- The measurement of interaction torques made at the joint level makes it indistinguishable, whose interaction caused the reading, be it a voluntary movement provided by the user or an involuntary interaction provided by the environment. In both cases, the control amplifies these effects regardless of the fact that the original stimuli were provided by the user.
- The sensor and the mechanical model assumed in the discussed work only deal with a rigid mechanical design model whose structures risk to be cumbersome and dangerous when the load to be carried/manipulated is high. Flexible designs may manipulate higher loads at the cost of more complex control design [70.38].
- The robustness of the control is demanded to the accuracy of the model and the design of the compensation gains. When no gain is programmed ($\alpha = \beta = 1$), the feedback is zeroed and the user perceives all the passive effects of the dynamics. Increasing these gains lowers the stability margin in a way that is dependent on the quality of the model approximation.

70.5.3 EMG Force Control and Power Augmentation

Notwithstanding the fact that EMG-based arms were already developed in the early 1980s, power-augmented systems based on EMG signals only appeared at the beginning of the 2000s. In 2001, *Rosen et al.* [70.116] proposed a powered exoskeleton system based on the myosignal analysis (as shown in Fig 70.19).

In order to associate a map between the myo-electric signals and the amount of exerted force, Rosen first detected the level of activation, then he applied a basic muscle contraction/elongation model as described by *Hill* [70.117] during his investigation on tetanic contraction and by *Winter* [70.60] for antagonistic muscle analysis. According to Hill's model, the force correlates the combined effects of muscle activation, muscle elongation, and muscle speed to a well-known state equation

$$F = \frac{aF_0(v_0 + v)}{(vF_0 + av_0)}, \quad (70.6)$$

where F is the force exerted by the muscle, v is contraction velocity of the muscle, F_0 is the maximum isometric force generated by the muscle, v_0 is the muscle maximum velocity, and a is the coefficient of shortening heat.

Such a model has been applied to all involved muscles $M_f = M_f(U_{\text{emg}}, \theta_m, \dot{\theta}_m)$, to determine the moment M_f induced on the elbow joint angle θ_m , by the muscle fibers f . In addition to the muscle bio-signal, the control closed loop used two more data from sensors: (1) a measurement of the external load and (2) the overall momentum applied by the operator on the exoskeleton.

The underlying basic idea is that the muscle signal operates as an external loop that provides a reference for an internal moment controller. The three gains in the controller K_L , K_H , K_u define, respectively, the internal loop force gain K_H versus K_L , and the overall EMG signal tracking bandwidth.

In a similar effort to the Rosen elbow extender, Kawai et al. [70.118] proposed a 1-DOF-actuated wearable device that lowers the internal backbone strain during pick-up tasks in order to prevent from lumbago. The device senses the average back angle (measured through a potentiometer) and the EMG strain on the thigh muscles. The motor control for the device is determined through a state machine based on a typical load pick-up and release procedure. The threshold values for switching between phases were determined through a test with a nominal load.

In [70.119] and [70.82], the EMG data are employed to control the HAL-3, walking assistant, and exoskeleton. The control algorithm is a combination of a finite-state machine with a torque control. Two force sensors placed in soles of the shoes serve to determine the floor-reaction forces and to switch among phases. Each phase is then used to determine in which mode the user knee is moving (active, passive or free). The joint motors are consequently controlled using Table 70.1

In different phases of motion, the joint control adopts a computed torque approach plus two components proportional to the myo-signals of flexion and extension

$$\begin{aligned} \tau_{\text{joints}} = & K_{\text{fl}} \text{EMG}_{\text{fl}} - K_{\text{ex}} \text{EMG}_{\text{ex}} \\ & + (I - M) \ddot{\theta} + (D - B) \dot{\theta} \\ & + C(\theta, \dot{\theta}) + K(\theta_0 - \theta), \end{aligned} \quad (70.7)$$

Table 70.1 The HAL dual-phase model. The phase 1 relates to the swinging leg and phase 2 relates to the stancing leg. In each phase, the table indicates the type of control to be implemented on the relative exoskeleton joint

Joint	Phase 1		Phase 2	
	Direction	Mode	Direction	Mode
Hip	Flexion	Active	Extension	Active
	Flexion		Flexion	
Knee	↓	Free	↓	Passive
	Extension		Extension	

where I and D are the inertia and viscous coefficients, respectively, as estimated through a recursive least squares auto regressive estimator (ARX) identification, C includes all Coriolis and gravity effects, M , B and K represent the target inertia, impedance to show to the operator. The term $\tau = K_{\text{fl}} \text{EMG}_{\text{fl}} - K_{\text{ex}} \text{EMG}_{\text{ex}}$ represents the estimated muscle torque whose conversion factors were determined through experimental tests.

The measure assistance level is close to 60% during flexion activities and to 85% during extension. In its most recent version, the HAL-5 adds contributes from accelerometers and gyroscope mounted on the backpack for better posture estimation [70.120]. HAL-5 extends the principle of operation of the lower body control to the user arm, by allowing the user to hold and carry an additional weight of 40 kg. HAL-5 extends the control with a greater number of phases (swing, landing, and support) and provides different control gains to optimize each phase [70.121].

The above EMG controllers only work fine when the developers are able to find two antagonistic muscles whose flexions and extensions can be directly related to the overall force exerted on a user joint (e.g., the biceps and triceps for the elbow joint). If this is not the case, Kiguchi et al. showed out how fuzzy controllers may estimate joint torques from several torques. In [70.122], they showed how to decode shoulder torques by combining the EMG signals recorded from eight different muscle sources. Such a fuzzy network has been coupled in the control of a 3-DOF mobile exoskeleton [70.123] to assist motion in highly impaired people.

70.5.4 Power Augmentation through Exteroceptive Sensors

High-force power augmentation systems require a different approach with respect to the proprioceptive and the EMG sensing approaches. In such devices, the flexibility of the structure and the high torques required at joints prevent the use of indirect measures of the force/torque exchanged between the device and the user. Moreover, the Hardiman approach, which integrated a master exoskeleton and an outfitting slave exoskeleton as a unique teleoperation system proved not to be functional [70.94].

Two systems have proved so far to reach this target in an operational and fully functional scenario: the Sarcos/Raytheon XOS Exoskeleton for the arms and legs [70.105] and the BE developed by PERCRO at Scuola Superiore Sant’Anna. Both of them are based on a similar working principle: the user body is directly attached to the exoskeleton in a predefined numbers of points, e.g. the two feet, the hands’ handles, and a shoulder harness for the BE; and additional interac-

tion at the pelvis for the XOS. The interaction forces exchanged between the exoskeleton and the user are measured at these points and used to simultaneously control equilibrium, force amplification, and motion control.

On the other side, the two systems differ for a number of technical details: the XOS design is light, adherent to the user body and based on rotary-hydraulic actuators, the BE instead mimics the weight distribution of the human body, the exoskeleton does not touch the user body except for the predefined contact points and can automatically adapt to different human percentiles, and finally, all the actuation structure is based on a unique high-torque electrical motorization.

Very few data are documented about the operation of the XOS system and much of the information available is contained within its related patents, instead the kinematics and the control of the BE are described in several documents [70.104, 124].

70.5.5 Control Schemes

The BE control is organized as a decentralized control, where each joint is supervised by a separate electronics. Figure 70.20 shows the PERECRO-BE device. All the electronics are organized in four clusters which respectively map to the single human limbs. The interconnection between joint controllers is achieved through four separate EtherCAT-buses.

All connections converge into a central electronics placed in the trunk backpack, which manages high-level control of walking, stability, and manipulation.

A unique type of motorization as well as a unique type of low-level controller is implemented in each joint. Figure 70.21 highlights the interaction between the internal control loops and the higher control level. The internal controllers operate at a very high rate (2.5 kHz) and provide to estimate the joint velocities. At limb extremities, these controllers also acquire the information recorded by the embedded force sensors. The modularity of the architecture and the structure of the information do allow a high scalability of the system and a regular scheduling of the local and higher controllers.

The two components highlighted in Fig. 70.21 as *force control* and *feed forward control* are managed at the central level at 1 kHz basic control rate. The first generates, using the sensor force information, a velocity command that is forwarded to each limb cluster, whereas the second combines force information with posture and velocity information to define feedforward commands that can be directly added to compensate weight, loads or other gravity/inertial effects on the exoskeleton joints.

Fig. 70.20 The PERECRO-Body Extender has been already defined (BE). The BE is a whole-body exoskeleton structure designed to lift and manipulate 50 kg load per arm in the worst case conditions. The device has five attachment points with the user body: the two boots, two handles embedded in the grippers and the trunk corset. In addition to the internal sensors (position, force, and gyroscopes), force sensors embedded in the attachment connection help to determine the proper motion commands

Given its flexible structure, the central controller can operate on the joint controllers in different operational modalities; among these are: admittance controller, impedance controller, and feedback linearization controller.

Admittance Controller

Different control strategies have been implemented to move both the upper arm and the lower body part of the exoskeleton. Four basic schemes of admittance controller are implemented to manage the exoskeleton during walking and manipulation activities:

- Arm admittance
- Swinging leg
- Stancing leg
- Double stancing leg.

The basic scheme is the arm-admittance controller. In this approach, the local force sensed at the inter-

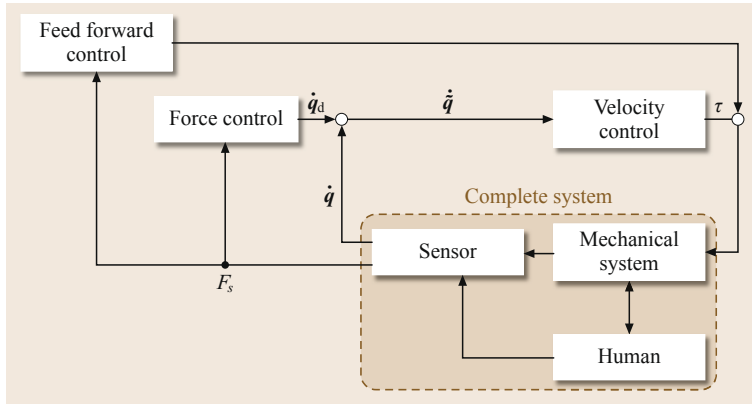

Fig. 70.21 The basic BE control structure. The internal velocity controllers are placed in the exoskeleton joints and locally perform a velocity servo loop (proportional derivative) which is enhanced by a direct feedforward torque. Both the inner-loop gain parameters and the external feedforward torque can be commanded from the higher level central control unit. This structure is repeated identically for all the exoskeleton joints

face is projected to the trunk reference system through the appropriate coordinate transformation. Its value is amplified through a gain factor and smoothed through a first-order low-pass filter that remove noisy effects. This reference signal is then back-propagated to the joint by using the inverse of the limb Jacobian.

$$\dot{q}_{Ld} = \mathbf{J}_L^+ \frac{p_f \mathbf{K}_{Lv}}{s + p_f} \mathbf{R}_h^{\text{Tr}} \mathbf{F}^h, \quad (70.8)$$

where \mathbf{F}^h is the handle force/torque vector as read by the sensor, \mathbf{R}_h^{Tr} is the rotation matrix that maps to the appropriate trunk reference system, \mathbf{K}_{Lv} is a force/velocity gain, p_f is the smoothing frequency, and \mathbf{J}_L is the appropriate limb Jacobian that describes the motion of the limb with respect to the trunk.

In addition to the above velocity commands, the control system also computes in real time the gravitational effects produced by the exoskeleton joints and provide to compensate them through the feedforward input (τ_{ff}) of the joint velocity controllers.

$$\tau_{\text{ff}} = \tilde{\mathbf{G}}(\mathbf{q}) \mathbf{R}_w^{\text{Tr}} \begin{bmatrix} 0 \\ 0 \\ 9.81 \end{bmatrix}, \quad (70.9)$$

where $\tilde{\mathbf{G}}$ is the gravity contribution matrix ($\text{DOF} \times 3$) that maps forces generated by the gravity to joints, \mathbf{R}_w^{Tr} is the rotation matrix that describes the arm orientation with respect to a world frame having the gravity vector aligned with the z -axis.

The motion behavior generated to the programmed feedback policy can be examined through a two-step analysis. The internal position controller can be made asymptotically stable through standard robust control techniques. While the external admittance loop, which involves the human operator, exploits an intrinsically passive behavior, through the display of a pure viscous

force to the operator. Hence, until the outer loop bandwidth is sufficiently smaller than the internal velocity servo, the two loops do not interfere [70.125].

The arm-admittance (70.8) scheme, also applies to floating legs which swing during walking. In such a case, the controller uses the forces measured by the booths which have been biased using offset values that ensure a stable contact among the user's foot and the exoskeleton booth.

During the standing phase, the information provided by the force sensors in the booth is useless. Hence the force sensor between the corset and the trunk backpack (backpack force) is used as a trajectory generator for the leg motion. The reference trajectories are generated with a unique, dual step, procedure which do not change being the exoskeleton standing on one or two legs.

In the first step, the *backpack force* has been determined. This force is filtered and amplified in the same way as for the handle admittance control. This operation generates a velocity vector ($\mathbf{v}_b, \boldsymbol{\omega}_b$) that applies to the backpack. In the second step, the central controller maps the same velocity vector to leg motion using a velocity map relationship that uses the direct kinematic between the trunk and the booths' soles. The kinematic vector, $\mathbf{r}_1(\mathbf{q})$, that describes the booth position with respect to the *backpack force* sensor is

$$\begin{cases} \mathbf{v}_f = \mathbf{v}_b + \boldsymbol{\omega}_b \wedge \mathbf{r}_1(\mathbf{q}), \\ \boldsymbol{\omega}_f = \boldsymbol{\omega}_b. \end{cases} \quad (70.10)$$

The approach maps the force felt by the corset backpack to the proper leg motion regardless the knowledge of the ZMP position.

Feedback Linearization Controller

The major limitation of the admittance control is the lack of transparency. The user who wears the power augmentation exoskeleton only feels forces that are proportional to his speed, and the feedforward component

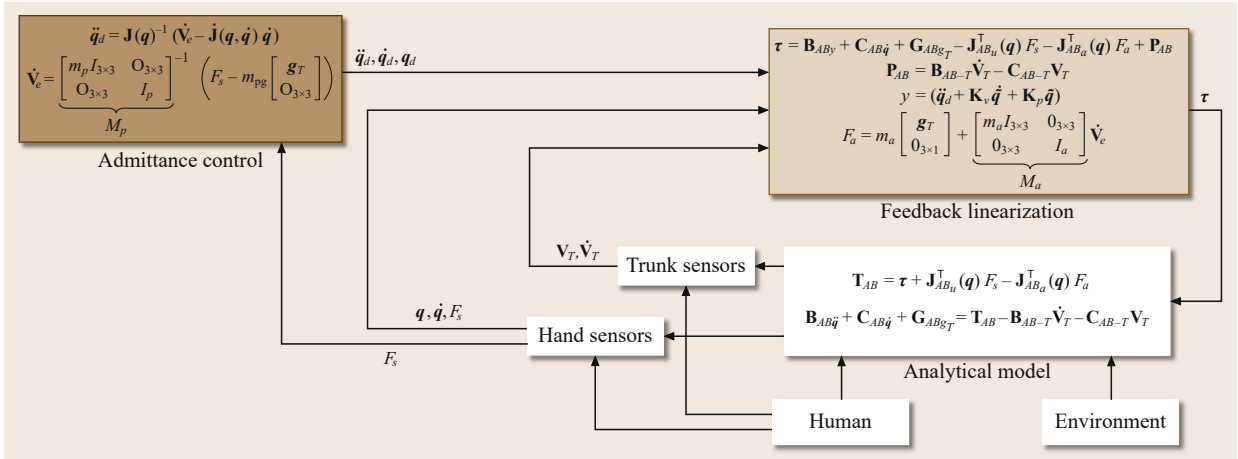

Fig. 70.22 The second-order admittance controller with feedback linearization. In this control scheme, the control input provided by the pilot generates a reference acceleration information for the limb. The feedback linearization provides to compensate the inertial/centrifugal/gravity effects of the exoskeleton and to map user input in proper acceleration information at the contact point. Moreover, the appropriate force amplification factor programmed at the sensor provide to establish an equilibrium among the environment interaction and the user commands

is only used to enlarge the control bandwidth and reduce the nonlinearity due to different postures.

However when the user touches any object, none of the contact force interferes with the exoskeleton motion creating in such a way an infinite force gain. While from the one side this is highly beneficial for joint stability, as a result it compromises the ability of the user to operate fine, scale force manipulation, tasks.

In order to recover this functionality, the BE implements on the same internal control structure two alternative control policies:

- A second-order admittance controller
- An admittance adaptive controller.

The second-order admittance controller collects user inputs to determine torque commands to the low-level joint controllers. This type of controller has been tested only on the upper body of the exoskeleton for the two relevant issues:

- The arms require greater manipulation capabilities and a better transparency
- The limited transparency of the leg motion reduces the interference between arm dynamics and trunk motion thus improving the overall stability.

The principle of operation for power augmentation is as follows (the related numerical equations have been reported in Fig. 70.22):

First, a force input is collected at each user handle. We suppose this force as being driven the interaction of

a virtual mass with the given inertia properties (m_p, I_p) and a separate weight property (m_{pg}).

Hence the resulting handle (end-effector) velocity (V_e) will be determined as a direct integration of the user force as applied on this virtual mass, and the joint velocities as direct differentiation of the motion Jacobian (box admittance control 70.22).

The feedback linearization control here comprehends four components:

- The $B_{AB} \ddot{y} + C_{AB} \dot{q} + G_{AB} g_T$ component, which takes into account the tracking error y , and the rotated gravity vector g_T
- The effective user force F_s , considered as being equal to the sensor read, and already applied on the exoskeleton structure
- The weight and inertial effects produced on the exoskeleton by the carried load (m_a, I_a) moved at the prescribed velocity (V_e)
- And the additional inertial and Coriolis effects provided by the moving trunk (P_{AB}).

As for the first-order admittance controller, the stability of the rigid model here can be ensured through the analysis of the linearized model. Combining the required equations, it can be derived that the robustness of the system is only affected by the amount of the inertia in the virtual mass properties (m_p, I_p). This property is unrelated from the power augmentation factor (m_a/m_p).

This is the reason why it is wise to decouple among the virtual mass (m_p, I_p) and the weight used for gravity

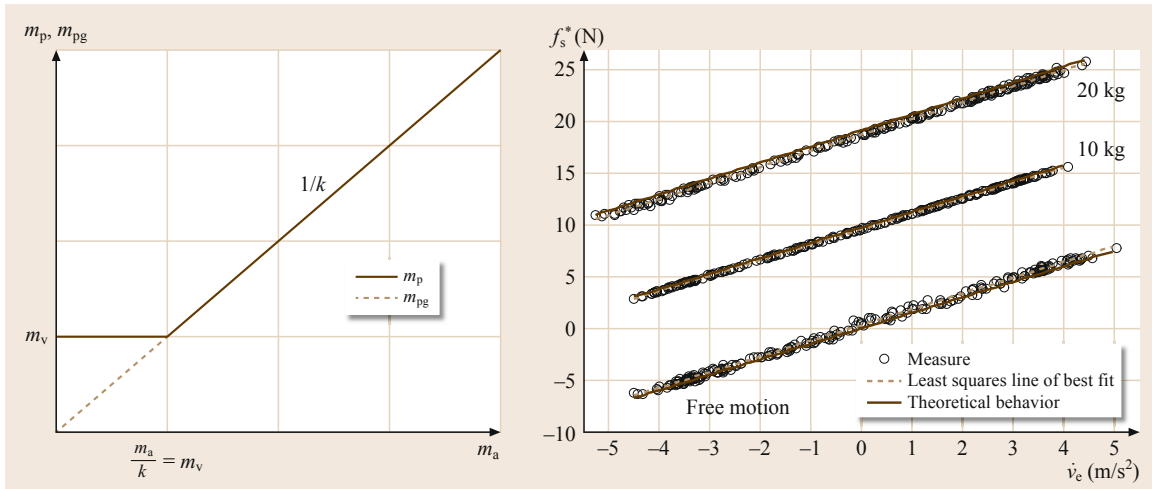

Fig. 70.23 Power augmentation profile. The power augmentation coefficient (k) is defined as the ratio of the carried load versus the perceived load. In the BE approach this ratio is represented as a piecewise linear approximation (left drawing). The quality of the control, tested on 1-DOF of the BE, has integrated with the adaptive policy and is shown on the right

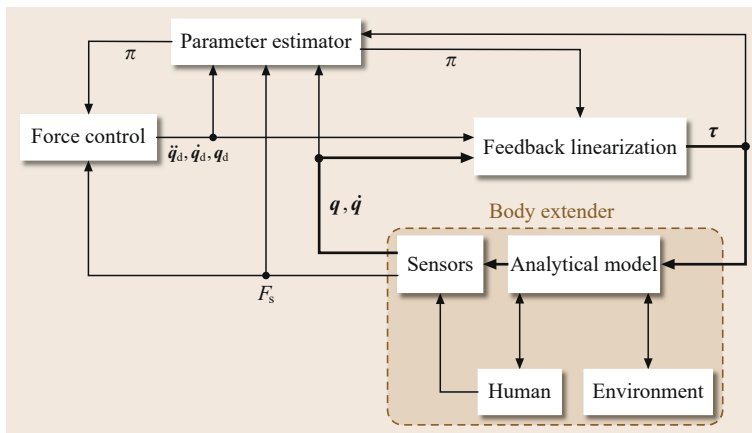

Fig. 70.24 The admittance adaptive controller with feedback linearization. A standard parameter estimator procedure has been applied to the robot structure in order to achieve online identification of the carried load. To simplify the computation and improve accuracy of estimation, the procedure assumes that the grasped object has regular mass properties and can be described with only two parameters as shown in Fig. 70.22

compensation (m_{pg}). The last not affecting the overall control stability.

Finally, the power augmentation factor has been defined as a piecewise linear approximation of the m_a versus m_p ratio which saturates for lower values of m_p in order to preserve overall stability (Fig. 70.23 left).

In order to work appropriately, the second-order admittance model requires an approximate estimation of the carried load (Fig. 70.23 right). It is supposed that this information to be subjected to the following conditions: the grasp is stable during manipulation, and the load does not change frequently.

Under these conditions, it is possible to use the motor currents as torque sensors that estimate the carried load. The principle of operation is reported in Fig. 70.24. Under the hypothesis that the load is stable and not frequently changing, the estimator can operate in lower frequencies.

Several tests to check the quality of estimation and the real-time adaptation to load change have been performed. In Fig. 70.24, the specific case of three different loads are reported. Attached to the video material of the present chapter the mass load/unload operation have been shown.

70.6 Conclusions and Further Developments

The presented review outlines some historical and state-of-the-art developments of wearable robotic systems for human–robot augmentation. Although EHPA systems are receiving an almost increasing interest from the robotics community, both from the research and from the commercial point of view, at present, the robotics technologies associated to their development are mainly derived from existing and well-established components. The lack of appropriate robotics components purposely developed for utilization on a *wearable* robotic system is mainly due, as testified by the existing research prototypes and commercial products, to a design approach that reflects the same methodologies pursued since the beginning for the design of industrial robots.

The design of a robotics system that must be worn by the human operator during a continuous operation also in unstructured environments should necessarily hamper design criteria, such as safety, fatigue, transparency, etc., that are only sometimes minimally considered for industrial robots.

From the above analysis of different typologies of EHPA systems, it comes out that the availability of adequate actuation components is fundamental to fulfill the basic functional requirements in terms of total weight, dynamics behavior, and control aspects. However, what is needed for the future research in this extraordinary

interesting and challenging field of research in robotics deals primarily with a new radical design philosophy centered on biomechanical aspects of humans behavior. In particular, a novel methodology considering as primary criteria the issue of energy consumption, not only for the wearable robotic system itself but also in terms of the complex resulting system human operator–wearable robot seems a fundamental prerequisite for future developments.

As indicated in the previous sections, so far true advantages of exploiting an EHPA system in different real-application scenarios are still to be demonstrated. In fact, so far, research developments have been primarily devoted to the physical design and realization of wearable robots, without addressing the successive phase of validation and performance assessment in a true real environment. This aspect should enter as a prominent component for future developments of the research on EHPA.

The field of wearable robots is rapidly expanding and the associated challenges in terms of design methodologies and ad-hoc robotics technologies just began to be understood in their full meaning. The motivations for future developments in this field should always firmly maintain human operator’s needs as the central focus of the research.

71. Cognitive Human–Robot Interaction

Bilge Mutlu, Nicholas Roy, Selma Šabanović

A key research challenge in robotics is to design robotic systems with the cognitive capabilities necessary to support human–robot interaction. These systems will need to have appropriate representations of the world; the task at hand; the capabilities, expectations, and actions of their human counterparts; and how their own actions might affect the world, their task, and their human partners. *Cognitive human–robot interaction* is a research area that considers human(s), robot(s), and their joint actions as a cognitive system and seeks to create models, algorithms, and design guidelines to enable the design of such systems. Core research activities in this area include the development of representations and actions that allow robots to participate in joint activities with people; a deeper understanding of human expectations and cognitive responses to robot actions; and, models of joint activity for human–robot interaction. This chapter surveys these research activities by drawing on research questions and advances from a wide range of fields including

computer science, cognitive science, linguistics, and robotics.

When people interact with each other, they draw on mental models of themselves, of their interaction partners, of the immediate context of the interaction, and of their broader physical, social, and cultural context. These models help them predict the actions of their interaction partners and make decisions about their own actions. To effectively interact with people, robots need similar models that help them determine their own actions and predict the actions of their users. *Cognitive human–robot interaction* (**HRI**) is a research area that seeks to improve interactions between robots and their users by developing cognitive models for

robots and understanding human mental models of robots.

A central tenet of cognitive **HRI** is that humans, robots, and the context of their interaction form a complex cognitive system situated in the real world. A key research activity in the field involves the development of frameworks to represent this system [71.1–3]. This activity is informed primarily by research in cognitive science that develops frameworks to represent human cognitive systems. These frameworks include physical symbol systems [71.4], situated actions [71.5,6], and those that combine symbolic and situated perspectives,

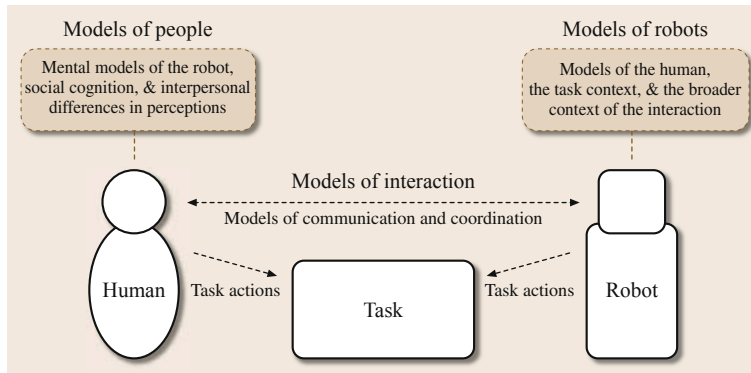

Fig. 71.1 A visual summary of the research activities in cognitive HRI

such as activity theory [71.7] and distributed cognition [71.8]. While the discussion on what framework best represents HRI as a cognitive system is ongoing, research in cognitive HRI involves the development of both symbolic and situated representations. More specifically, research activities in this area include (also illustrated in Fig. 71.1):

1. *Human models of interaction:* Building an understanding of people's mental models of robots, how people perceive robots and interpret their actions and behaviors, and how these perceptions and interpretations change across contexts and user groups.
2. *Robot models of interaction:* The development of models that enable robots to map aspects of the interaction into the physical world and develop cognitive capabilities through interaction with the social and physical environment.
3. *Models of HRI:* Creating models and mechanisms that guide human–robot communication and collaboration, action planning, and model learning.

This chapter surveys existing efforts in these research areas, drawing on research questions and advances from a wide range of fields including robotics, cognitive science, and linguistics.

71.1 Human Models of Interaction

Robots are expected to increasingly enter everyday environments – outside of factories and laboratories – including homes [71.9, 10], offices [71.11], and classrooms [71.12, 13]. In these contexts, robots will need to coexist and collaborate with a wide variety of users, such as children and the elderly, many of whom will not be technically trained. Accordingly, there is a growing research emphasis in cognitive HRI on identifying the mental models people use to make sense of emerging robotic technologies and investigating people's reactions to the appearance and behaviors of robots. This research aims not only to improve the ease of use of robots by designing them to fit human mental models, but also to gain new insights about human cognition and behavior. With the latter goal in mind, researchers also use robots to embody specific theories of human cognition that are then evaluated through HRI studies.

71.1.1 Mental Models of Robots

Research in human–computer interaction has shown that people's attitudes and behaviors toward digital technologies often follow the social rules established in

human–human interaction [71.14]. It is reasonable to expect that people will similarly interpret the interactive behaviors of robots in social ways. Cognitive HRI researchers continue to investigate the extent to and conditions in which this maxim applies to HRI as they use their understanding of human social cognition to develop robotic platforms adapted to users' expectations and behaviors. In the process of evaluating such robotic platforms, researchers explore people's mental models of robots and identify areas in which users' expectations and understandings of robots may not be born out by the robot's appearance or behavior in ways detrimental to the HRI experience. Knowing which mental models people are using to interpret robot behavior not only helps roboticists to understand HRI more deeply, but also helps them in designing appropriate behaviors for the robot.

Models Ascribed to Robots

Extensive research by Turkle et al. [71.15, 16] examines how people, including children and older adults, make sense of their novel interactions with social robots such as Kismet, Cog, PARO, Furby, and My Real Baby.

These studies show that people apply a variety of mental models relating to animacy, sociality, affect, and consciousness to explain their experiences and emerging relationships with robots. Some research participants approached robots in a scientific-exploratory mode, interpreting a robot's actions in an emotionally detached and mechanistic manner. Others took a relational-animistic approach, investing in the interactions emotionally and treating robots as if they were living beings, such as babies or pets. The ways in which participants described the robots verbally did not always fit with the way in which they interacted with them – a person who says the robot is *only a mechanical thing* may still act toward the robot in a nurturing manner, such as soothing a crying My Real Baby [71.16, p.118]. This corresponds to previous findings in human–computer interaction (HCI) which suggest that people *mindlessly* apply social characteristics to computers [71.17]. Field studies with the seal-like robot PARO have shown that robots can also act as *evocative objects* that spark reflections on previous relationships and events (e.g., with a grandchild, spouse, or pet), which users then use to make sense of their interactions with the robots [71.18, 19].

In addition to identifying the mental models people use to interpret their experiences with robots, researchers study the effects from deliberately incorporating specific social schemas into robot design. *Anthropomorphism*, or the attribution of human characteristics to nonhuman (e.g., animal or artifact) behavior, is an interpretive schema that has been of particular interest to HRI researchers. Some scholars, such as Nass and Moon [71.17], critique anthropomorphic explanations as false and misleading. Others, including Duffy [71.20] and Kiesler et al. [71.21], suggest that the deliberate use of anthropomorphism can benefit social robot design by taking advantage of people's propensity to interpret events and other agents socially to make robot behaviors more understandable to users. This interpretation raises the question of which characteristics of the robot or the interaction are instrumental in inciting people to anthropomorphize robots and has inspired researchers to study a variety of socio-cultural cues, behaviors, and task contexts. Kiesler et al. [71.21] showed that people anthropomorphize a physically embodied robot more readily than an on-screen agent, and people behave in a more engaged and socially appropriate manner while interacting with the co-present robot. People also anthropomorphize robots they interact with directly more than they do with robots in general, and with robots that follow social conventions (e.g., polite robots) more than those that do not [71.22]. The personal characteristics, such as personality, of the human interaction partner can also affect their mental models of robots. For example, users with low emotional stability and extraversion

scores were found to prefer mechanical-looking robots to human-like ones [71.23].

As might be expected, a robot's human-like appearance can have a positive effect on people's propensity to anthropomorphize [71.25]. Obversely, too high a level of human-likeness may place the robot in the *uncanny valley* [71.26]. The *uncanny valley* refers to a dip in the hypothetical nonlinear graph describing the relationship between a robot's human-likeness and a human's emotional response to it, suggesting that a robot with a very high degree of human-likeness coupled with some remaining nonhuman qualities will make users uncomfortable. This hypothesized effect essentially describes what happens when a person's mental model of the robot as human is not born out by its interactive capabilities. Various cognitive aspects of this hypothesis have been studied, suggesting that the construct is multidimensional [71.27, 28] rather than two-dimensional (2-D), as depicted by Mori [71.26]. Furthermore, research suggests that the mismatch between different dimensions, rather than any quality alone, can cause a dissonance that leads to people's discomfort with robots. MacDorman et al. [71.24] show that incongruencies between a robot's appearance and movement can diminish anthropomorphic attributions (Fig. 71.2). A similar result was found by Saygin et al. [71.29], who used functional magnetic resonance imaging (fMRI) to show that the human action perception system made distinctive responses to the mismatch between the level of human-likeness of a robot's appearance and motion but not to appearance or motion alone. Mismatches in the human- or robot-like qualities of an on-screen robot's voice and appearance were also shown to heighten people's sense of the character's eeriness – people found

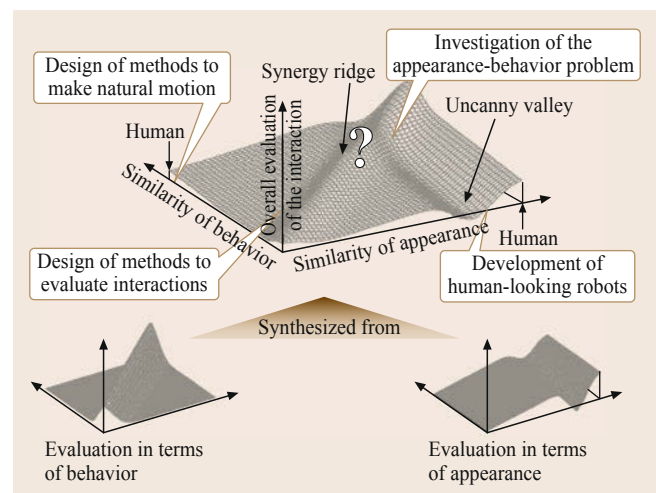

Fig. 71.2 An extended notion of the uncanny valley which includes appearance and behavior as significant variables (after [71.24])

both a robot with a human voice and a human with a robot voice to be creepy [71.30].

Mental Models in Robot Design

Researchers may deliberately include specific anthropomorphic schemas to promote user behaviors that aid robots in performing their tasks. One common example is the use of the *baby schema* – a soft round appearance, large eyes, and proto-verbal utterances – in Kismet [71.31] (Fig. 71.4), Muu [71.32] (Fig. 71.3), and Infanoid [71.33] to encourage people to anthropomorphize robots. This schema is also useful in that it can incite people to behave in a nurturing manner toward robots in the interest of scaffolding the robots' learning in a way similar to infant–parent interactions. A robot's *perceived* gender can also have an effect on people's mental models of the robot's knowledge of certain topics; for example, in one study a female robot was expected to be more knowledgeable about dating than a male robot [71.34]. While certain mental models become operational as soon as a person starts interacting with a robot (e.g., gender, age, human-likeness), people can adapt their mental models of a robot's capabilities when given additional information about the robot's personal characteristics, such as the robot's country of origin or the language it speaks [71.35]. Goetz et al. [71.36] showed that matching a robot's *personality* to the task it is supposed to perform can have a significant effect on its efficacy: people were more responsive to a robot that had a serious, rather than an entertaining, demeanor when its job was to motivate them to exercise. Also focusing on *task models* in HRI, Lee et al. [71.37] showed how people use their existing utilitarian and relational models of service to set expectations for their interactions with a service robot. These models also affected the preferred ways in which the robot should make up for any mistakes it makes in service – people with a utilitarian mental model of service preferred to receive compensation, while those with a relational model responded well to an apology.

As interactive robots are developed and used all over the world, researchers have also started exploring how *cultural models* [71.38] affect people's perceptions of and interactions with robots. Social and behavioral norms are culturally variable, so we can expect users' understanding and adoption of socially interactive robots to differ accordingly. Cross-cultural research in HRI largely supports this expectation. Evers et al. [71.39] showed that users from China and the US respond differently to robots. Further research by Wang et al. [71.40] suggests that specific cultural models regarding communication norms, particularly explicit and implicit modes of communicating information and intent to interaction partners, affect people's

Fig. 71.3 Muu's big eyes and soft round body are designed according to the *baby schema*. Using two robots that can interact with each other instead of one suggests a relational understanding of agency (courtesy of Šabanović)

Fig. 71.4 Kismet's big round eyes and infant-like vocalizations are another example of the *baby schema* (courtesy of Šabanović)

perceptions of a robot's trustworthiness and its in-group membership. Researchers have also shown that roboticians themselves use cultural models unintentionally in their work, including particular models of emotional display [71.41], and cultural models reflecting historical, theological, and popular perceptions of robotic technology [71.42]. Research on cultural models in HRI not only points to the importance of reflexively including such models in robot design, but also allows researchers to do systematic research on culturally situated cognition using robots as stimuli.

Research on mental models applied to interactive robots has not only shown that people use their existing mental models to make sense of these novel artifacts, but also that we may need new *ontological*

categories to accommodate emerging mental models of these entities [71.16, 43]. Kahn's et al. [71.44] studies of children's moral interpretations of interactions with an AIBO robot showed that their mental models of the robots included rationalizations and behaviors related to both inanimate and animate objects. *Turkle* [71.45] suggests that interactive robots co-opting relational feelings and responses normally reserved for animals and humans call into question the authenticity of relationships. Further, *Turkle* [71.45] suggests that a more sophisticated new notion of autonomous yet inanimate artifacts has become necessary. Both researchers have suggested that interactive robots might comprise a new ontological category, and that we also need to be conscious of the ways in which interactions with these artifacts affect our mental models of animate beings.

71.1.2 Social Cognition

The development of robots that can interact naturally with humans calls for the detailed study of social activity and the cognitive models that underly such activities. *Scassellati* [71.46] argues that robots can help us study the limits of human social cognition because they are not alive, yet they can behave in socially appropriate (or inappropriate) and evocative ways. Robots that incorporate social cues such as gaze, proximity, and facial expressions, push our *Darwinian buttons* [71.16, p. 8] and effectively coerce us into interacting with them socially. Studying which cues have these effects is an opportunity to learn more about human social cognition and improve robot design.

Researchers studying the social aspects of cognitive HRI are identifying the minimal cues robots need to evoke social responses from people, including those related to robotic embodiment, gaze, proxemic cues, and interaction rhythms. Current research is also focused on applying and evaluating different models of cognition in the context of HRI. Robots can be unprecedented experimental tools for the study of social cognition. They can be used to provide stimuli in experiments and field studies, since their actions and behaviors can be carefully controlled, finely tuned and varied, and repeated exactly and indefinitely, which is often challenging even for well-trained human confederates [71.47, 48]. Furthermore, robots do not have difficulty acting *unnaturally* (e.g., not reacting to other person's cues) or violating social norms (e.g., being rude) when needed, a source of potential stress in human researchers [71.49].

Minimal and Human-Like Cues in HRI

One approach to studying social cognition has been to try to isolate the *minimal* set of cues that evoke social

responses and perceptions from human interaction partners. The creators of Muu followed a *minimal design strategy* [71.32], using cartoons and children's drawings to develop a robot that can be communicatively engaging to people without relying on overt human-likeness. *Kozima* et al.'s [71.50] *Keepon* was designed to include characteristics common to living beings, such as lateral symmetry and two eyes, which are assumed to be important for social interaction (Fig. 71.5). The robot also performs fundamental social behaviors, such as joint attention, eye contact, and emotional expression through bodily posture and movement and using only four degrees of freedom (Fig. 71.6). These minimal cues have been shown to be sufficient for engaging children in short-term interaction in the lab and long-term interaction in more natural environments, such as a classroom [71.50].

Studies with minimalist robots have also underscored the effect of *social context* in people's interpretations of robots. Field studies with *Keepon* in an elementary school showed that children incorpo-

Fig. 71.5 Keepon is a simple robot used to investigate cues such as joint attention, emotive expression, and rhythmicity in HRI (courtesy of Šabanović)

Fig. 71.6 Keepon uses four degrees of freedom to express emotive and attentional cues (after [71.50])

Fig. 71.7 An android robot fabricated by Kokoro Ltd. (courtesy of Šabanović)

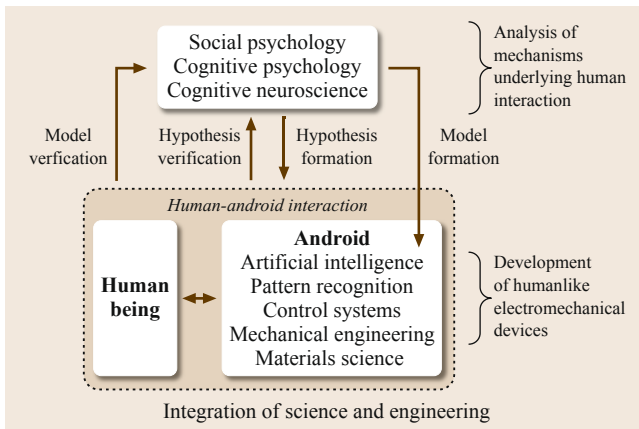

Fig. 71.8 Androids can be used to investigate human cognition analytically as well as synthetically (after [71.51])

rated the simple robot into a wide variety of interaction contexts (e.g., playing house with Keepon as

a baby or pet, or treating Keepon as another student in the classroom) due not only to its interpretive flexibility, but to the richness of the social environment. This inspired children to engage with the robot over long periods of time, sometimes years, whereas they became bored after 10–15 min when interacting with Keepon in the laboratory. The above mentioned Muu’s design was inspired by ecological models of cognition [71.52, 53] suggesting that a robot is inherently incomplete as a communicative device – it needs a human interaction partner to imbue its actions with meaning. Muu therefore relies on the context and the presence of other interactive agents (including people, other Muu, and objects such as blocks displayed in Fig. 71.3 for triadic interaction) to enable people to make sense of its actions and relationally ascribe social agency to the robot. The Social Trash-can project [71.54] similarly explored how minimal social cues, including contingent motion and approaching people, can be used to display the robot’s intentions to children and get their assistance in trash collection. Yamaji et al. [71.54] also showed that robots moving together as a group – relationally – were more successful in attracting the children’s attention than that moved individually.

An alternative approach to the study of social cognition through HRI focuses on *human-like realism* in appearance and behavior and is proposed by Ishiguro [71.47] and MacDorman and Ishiguro [71.48]. They claim that androids – robots that bear a close and sometimes *uncanny* resemblance to humans (Fig. 71.7, for example) – are unprecedented test beds for the study of social cognition. Used as stand-ins for humans in this *android science*, robots have a twofold function as experimental tools for evaluating hypotheses about human perception, cognition, and interaction, and as a testing ground for various cognitive models (Fig. 71.8). Using an android platform, Ishiguro [71.55] showed the importance of micro movements as a cue that incites people to attribute human-likeness to a robot in short (1–2 s) interactions. Another topic of continuing investigation is the possibility of simulating the personal presence of a remote actor in the local environment using an android platform [71.56, 57]. Shimada et al. [71.58] showed that people evaluated an android as more likable when it mimics them in a way similar to the *chameleon effect* that occurs when two people interact. MacDorman and Ishiguro [71.48] suggested that such androids can be used in research relating to a number of current topics of interest in cognitive science, including the mind-body problem, nature versus nurture, rationality and emotion in human reasoning, and the relationship between social interaction and internal cognitive mechanisms.

Embodied Social Cues

Embodiment separates robots from other interactive digital technologies and has been investigated through studies comparing how people interpret and act toward robots that are physically co-present with them and on-screen robots or social agents. Wainer et al.'s [71.59] comparison of people's interactions with an embodied robot and a simulated robot, and a co- and tele-present found that people were more engaged with, behaved more appropriately to, and anthropomorphized a co-located robot more than a tele-present robot. People interacting with an embodied robot have also shown tendencies to issue more commands than those interacting with a simulated robot [71.60]. The social effect of embodiment in HRI was further confirmed by Bainbridge's et al. [71.61] study showing that people are more likely to comply with requests made by an immediately present robot rather than requests made by a remote robot communicating with them through a television screen. These converging results strongly suggest that a robot's embodied presence has a significant cognitive effect on people's social responses to the robot. The embodied nature of robots also enables the study and use of various other social cues, including proxemic behaviors, gaze, and interaction rhythms, in HRI. A more detailed review of embodied social cues is provided by Mutlu [71.62].

Proxemic behaviors [71.63], the study of which is enabled by the embodied nature of robots, not only have a significant effect on people's perceptions of and behaviors toward robots, but have also been used as a measure of people's perceptions of robots as social agents. Takayama and Pantofaru [71.64] found that prior experience with pets and robots decreased the distance at which people felt comfortable around robots. Individual traits such as gender and personality also affect people's preferences regarding the distance at which they are comfortable with a robot approaching them [71.64, 65]. Proxemic behavior can be related to other social cues in complex ways. For example, Mumm's and Mutlu's [71.66] study showed that people will compensate for the intense gaze in their direction of a robot they do not like by moving away from the robot (Fig. 71.9). While most studies of proxemic systems have been done in the laboratory, recent work is also investigating more natural interactions between humans and robots in open environments [71.67].

Gaze is an important cue in human–human interaction and is also one of the most studied nonverbal social cues in HRI (👁️ VIDEO 128). People use many such seemingly unintentional, unconscious, and automatic nonverbal cues as clues regarding the mental states and intentions of other actors, including robots. Gaze has been shown to be useful for communicat-

Fig. 71.9 In the study by Mumm and Mutlu [71.66], participants maintain a greater distance with the unlikable robot when the robot follows them with its gaze than when its gaze avoids the participant, while their proxemic behavior is not affected by a likable robot's gaze (courtesy of Mutlu)

ing intent, modulating interaction, and even affecting participants' experience and memory of the interaction. Researchers have shown that gaze can be used to engage users [71.69, 70] and to assign them particular roles in and manage the interaction [71.71]. A robot's gaze behavior can affect the human interaction partner's gaze and speech, their comprehension of the robot's speech [71.72], and people's memory of a story narrated by the robot and perceptions of the robotic storyteller [71.73]. Researchers studying the temporal aspects of gaze in HRI found that the timing of gaze behavior provides cues to human intentions while teaching the robot the names of objects, suggesting that properly timed gaze behaviors can have a positive effect on collaborative tasks between a human and a robot [71.68] (Fig. 71.10). Yu et al. [71.74] have developed a data-driven approach to analyzing human gaze in the context of HRI, which can be used

Fig. 71.10 Yu's et al. [71.68] HRI studies provide data for developing models of the temporal aspects of interaction (courtesy of Yu)

to develop detailed micro-behavioral gaze models that can guide robot behaviors as well as be used to understand human intentions and behaviors in the course of collaborative activities. A recent study by *Admoni et al.* [71.75], contrary to the assumption that anthropomorphic robots engage us automatically in much the same way we are engaged by people, shows that robot gaze is not necessarily treated by people in the same automatic way that human gaze is treated; we do not, therefore, necessarily perceive robots as social in an automatic and *mindless* way.

Interaction rhythms – nonverbal and largely unconscious temporal coordination between partners in an interaction – enable the exchange of information, anticipation of the interaction partner’s actions, and even positive evaluations of interaction among humans as a fundamental subtopic of all human interaction [71.76–78]. The rhythmicity of interaction is therefore also a crucial factor in *HRI*, both in terms of developing robots that can perceive and respond to people’s rhythmicity, and of understanding how people react to the temporal aspects of robot behaviors. *Michalowski et al.* [71.79] used a dancing robot to explore the rhythmic properties of social interaction and showed that children were more likely to interact with a robot that was synchronized to background music rather than one that was not, and that the children’s own rhythmic behavior was influenced by the robot’s rhythmicity. In further research, *Michalowski et al.* [71.80] suggest that rhythmic interaction can be used as a form of play between children and robots, and that following the robot’s lead in rhythmic entrainment with music causes children to attend more closely to musical rhythm. *Avrunin et al.* [71.81] found that simple changes in a robot’s rhythmic dancing behavior, such as variation of motions, flaws in the robot’s synchrony with music, and coordination of behavior changes with musical dynamics, increased people’s perceptions of the robot’s lifelikeness. *Hoffman and Breazeal* [71.82] used the temporal patterns of interaction – its rhythms – to develop robotic systems that can anticipate a human partner’s actions in collaborative tasks, such as *AUR*, a robotic desk lamp, and *Shimon*, a marimba playing robot [71.83] ( VIDEO 236). Along with improving *HRI*, the use of robots in studying the rhythmic properties of interaction provides a new

tool for cognitive science research on these subtle, fine grained, and unconscious social cues.

Cognitive Development in *HRI*

A further topic of focus in cognitive *HRI* has been the study of social and cognitive development through studies of typically developing and autistic children’s interactions with robots. Multiple studies in educational contexts have focused on understanding how children ascribe social agency to robots [71.12, 13]. *Kozima et al.* [71.50] found that children of different ages display varying modes of interaction with the robot, which suggest different levels of comprehension of its ontological status – 0-year-old interacted with *Keepon* as a moving thing, 1–2-year-old interacted with the robot as an autonomous system, and children over 2 years of age treated the robot as a social agent. *Deák et al.* [71.84] studied the mechanism of joint attention in *HRI* to explore the importance of contingency and find out which perceptual features infants use to achieve shared attention by modeling these in a robot. Researchers also use robots to study social deficit disorders, particularly autism. Converging results on research using robots to study social deficit disorders show that autistic children respond to robots in a social manner that they do not display with people [71.85–87], inspiring researchers to perform studies with children in the context of *HRI*. One aim of such research is to try to understand which aspects of a robot’s behavior enable autistic children to participate in social interaction, which may clarify some of the reasons for their difficulties when interacting with humans. *HRI* researchers have also applied robots to various therapeutic scenarios with autistic children in an effort to provide parents and therapists with a tool to improve communication and understand the children better [71.88, 89]. Studies by *Kozima et al.* [71.90] in which the robot *Keepon* interacts with children with autism suggest that such minimally designed robots can be used to motivate autistic children to share their mental states with others, such as therapists or parents. This work poses a promising possibility for learning more about social deficits and development disorders such as autism, as well as providing tools for diagnosis and therapy using robotic technologies.

71.2 Robot Models of Interaction

Simon [71.91] suggests that the study of human behavior can be approached through synthesis as well as analysis and designs computer simulations as a technique for understanding and predicting the behavior of

natural, social, and cognitive systems. In the spirit of *Simon*’s synthetic approach to the study of human cognition, robotics researchers have been engineering robots as tools for developing and testing a variety of cog-

nitive, behavioral, and developmental models [71.47, 92, 93]. This approach assumes that cognitive models are validated when the implementation of a particular model on a robot produces behavior similar to that produced by humans in the same situation; if this does not occur, it is a sign that there may be something wrong with the model or the way it was implemented in the robot [71.46]. Cognitive HRI research involves the development of robotic platforms based on findings from cognitive science and using such platforms to extend knowledge about human cognitive processes.

71.2.1 Developmental Models

Robots are particularly appropriate for exploring theories of embodied and social cognition, which emphasize the centrality of the agent's interactions with its environment and other agents in that environment to cognitive functioning. In the process of synthesizing a robotic system, the researcher is drawn to focus on the dependency of cognition on noncognitive processes, including the social and physical environment in which cognition takes place. Robots such as Cog and Kismet [71.31] have been used to simulate and validate different theories of cognition, perception, and behavior. Cog was used to implement and test cognitive models relating to reaching behavior, rhythmic motor skills, visual search and attention, and social skill acquisition (e.g., joint attention and theory of mind). In the process they were able to validate, extend, and show the limitations of cognitive, behavioral, and developmental theories. In later projects, researchers have developed models inspired by human cognition and behavior such as social referencing [71.94], perception and action loops [71.95], anticipatory actions in collaborative teamwork [71.96], and others.

Robotics researchers apply the idea that the development of intelligence is embedded in social and cultural environment to the construction of robotic artifacts. For example, Breazeal [71.31] applied theories relating to infant social development, psychology, ethology, and evolution to design the robot Kismet, which used infant-like social cues to engage a human participant in interactions that would scaffold the robot's learning, as in the case of infant–parent interactions. Researchers have also developed a variety of robotic systems that exhibit cognitive traits such as imitation [71.97, 98], joint attention [71.99–101], and rhythmic synchrony [71.50, 102]. The Infanoid project [71.33] also used a synthetic approach in which development was understood through studying how the robot learns. Situated and embodied models have been applied to robot learning, particularly through imitation. For example, Bakker and Kuniyoshi [71.103] pro-

pose *imitation* as an interaction and learning paradigm in contrast to *robot programming* or *robot learning*. Further, they argue that robot programming is too hard and tedious to specify complex behaviors in sufficient detail and specify how they might be adapted to novel situations.

71.2.2 Robot Spatial Cognition

Systems dedicated to modeling spatial language and interaction, including the theories by Jackendoff [71.104], Landau and Jackendoff [71.105], and Talmy [71.106], have been produced for many years. Several previous works have been computational instantiations of the ideas presented in these theories, in particular the implementation and testing of spatial semantics models. Regier [71.107] built a system that assigns labels, such as *through* to a movie showing a figure moving relative to a landmark object. Kelleher and Costello [71.108] and Regier and Carlson [71.109] built models for the meanings of static spatial prepositions, such as *in front of* and *above*.

Many authors have proposed formalisms for enabling systems to reason about the semantics of natural language use in the context of giving directions. For example, Bugmann et al. [71.110] identified a set of 15 primitive procedures associated with clauses in a corpus of spoken natural language directions. Levit and Roy [71.111] designed *navigational informational units* that break down instructions into components. MacMahon et al. [71.112] represented a clause in a set of directions as a compound action consisting of a simple action (move, turn, verify, and declare-goal), plus a set of pre- and post-conditions. Many of these previous representations are expressive but difficult to automatically extract from text. Some authors avoid this problem by using human annotations [71.111, 112] or by specifying the robot's behavior in a controlled language [71.113]. Matuszek et al. [71.114] created a system that follows directions using a machine translation approach. Similarly, Vogel and Jurafsky [71.115] used reinforcement learning to automatically learn a model for understanding route instructions.

71.2.3 Symbol Grounding

Mapping language from the human partner to aspects of the external world – locations, objects, or actions the robot should take – described by the language was referred to as an instance of the *symbol grounding* problem [71.116]. There are three different ways people have approached the symbol grounding problem, which is more general than spatial cognition, in robotics. Starting with Winograd [71.117], many have created symbol

systems that map between some language and the external world by manually connecting each term onto a pre-specified action space and set of environmental features [71.110, 112, 113, 118–121]. This class of systems takes advantage of the structure of linguistic interaction, but the systems usually do not involve learning, have little perceptual feedback, and have a fixed action space. A second approach involves learning the meaning of words in the sensorimotor space (e.g., joint angles and images) of the robot [71.122–124]. By treating human interaction terms as sensory input, these systems must learn directly from complex features extracted by perceptual systems, resulting in a limited set of commands that can be robustly understood. A third approach is to use learning to convert from an interaction onto aspects of the environment. These approaches may only use linguistic features [71.125, 126], spatial features [71.107] or linguistic, spatial, and semantic features [71.114, 115, 127–129]. These approaches learn the meaning of spatial prepositions (e.g., *above* [71.107]), verbs of manipulation (e.g., *push* and *shove* [71.130]), and verbs of motion (e.g., *follow* and *meet* [71.131]) and landmarks (e.g., *the doors* [71.129]).

Recent progress in probabilistic relational models, such as the generalized grounding graph (G^3), has addressed these issues by exploiting the structure of

spatial discourse, breaking down a natural language command into component clauses and connecting each word to a physical interpretation [71.131, 132]. The grounding graph takes full advantage of the hierarchical and compositional structure of natural language commands and is able to ground landmarks, such as *the computers*, by exploiting object co-occurrence statistics between unknown noun phrases and known perceptual features, spatial relations, such as *past* in the path of an agent relative to an object, and motion verbs, such as *follow*, *meet*, *avoid*, and *go* in the path of a single agent or multiple agents. Once trained, the G3 model can ground spatial discourse in a semantic map of the environment; the map can be given a priori or created on the fly as the robot explores the environment. The G3 model is dynamically instantiated as a hierarchical probabilistic graphical model that connects each element in a natural language command to an object, place, path, or event in the environment. Its structure is created according to the compositional and hierarchical structure of the command, learning the mapping from language onto a continuous robot plan. The G3 model is trained on a corpus of natural language commands paired with groundings, and learns meanings for words and phrases in the corpus, including complex verbs, such as *put* and *take*.

71.3 Models of Human–Robot Interaction

Robotic technologies that interact with people – whether they afford closed-loop teleoperation or collaborate autonomously as peers – need to interpret, make decisions about, and respond to their environment, particularly the physical world, the task that they are expected to support, and the actions, goals, and intentions of the other agents – including people. To achieve these goals, robots need *models* that accurately represent the physical and cognitive characteristics of their environment. These models might outline such characteristics as narrowly as control–action relationships in the context of teleoperation or as comprehensively as human–robot joint activity in the context of peer-to-peer collaboration. Cognitive HRI considers the

robotic system to be a part of a distributed cognitive system and therefore seeks primarily to develop cognitively inspired models [71.2]. These models might draw on knowledge about human cognition to improve the usability of robotic system, mimic human decision making or behavior mechanisms, or represent the complete human–robot cognitive system, offering cognitive representations for different paradigms of HRI (Fig. 71.11).

71.3.1 Dialog-Based Models

Research on human robot interaction across different interaction paradigms from teleoperation [71.133, 134]

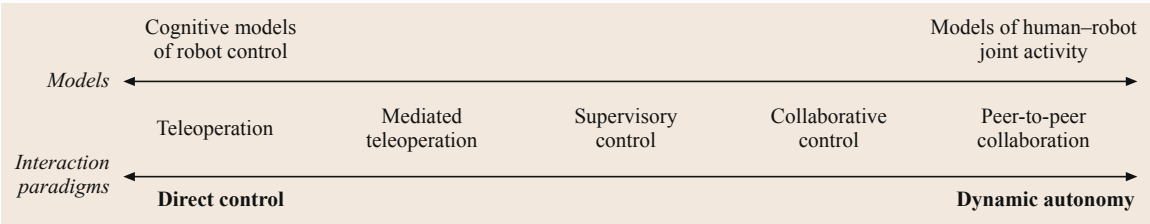

Fig. 71.11 Different paradigms of HRI (after [71.2])

to peer-to-peer interaction [71.135] has highlighted the need for establishing *common ground* [71.136] for effective HRI. In the context of teleoperation, Burke et al. [71.133] found that a lack of appropriate shared representations among human team members and the robot resulted in discrepancies in understanding among team members and breakdowns in perceiving and interpreting data provided by the robot. Stubbs et al. [71.134] observed such lack of common ground between operators and the robot across varying levels of autonomy. In the context of peer-to-peer interaction, Kiesler [71.135] argues that participants in an encounter seek to minimize their collective effort to reach mutual understanding and that the effort needed to establish this understanding between a robot and its users might determine the outcomes and success of HRI. These examples have motivated a large body of research in developing dialog-based models for establishing common ground in human–robot joint activity.

An example of the application of a dialog-based model to a task domain that traditionally involved supervisory control is Fong's et al. [71.136] *collaborative control* system. In this system, the human and the robot collaborated as partners to perform tasks such as navigation, collaborative exploration, and multirobot teleoperation and achieve shared goals within these tasks. The interaction between the robot and its human counterpart involved engaging in dialog to share information and control at key points in the task. For instance, when the robot encountered an obstacle, it asked the user, *Can I drive through <image>?* along with an image of the obstacle. In asking these questions, the robot drew on specific attributes of the user, such as response accuracy, expertise, availability, efficiency, and preferences to determine whether or not it should direct specific questions to its user.

A number of proposed models and systems take the dialog-based interaction paradigm further to involve the robot and its human counterpart jointly addressing the domain task and dialog itself as *joint action* [71.137, 138]. In this peer-to-peer setup, either party selects goals to address and strategies to be used to address them and either party performs any part of the task. The model proposed by Foster et al. [71.137] includes a semantic interpretation module and a central decision-making module which draw on resources, such as a history of the ongoing discourse between the robot and its user, a world model, a domain planner, and a representation of the plan that is currently being executed, in order to generate action and communication behaviors.

The model proposed by Li et al. [71.138] draws on joint intention theory [71.139], considering the joint activity to involve a common persistent goal of achieving conversational grounding, and explicitly uses elements

of grounding in representing conversational contributions. These contributions involve a *presentation* and an *acceptance* phase. For example, when an agent asks a question and the other agent answers, the question becomes the presentation and the answer becomes the acceptance, forming a *grounded exchange*. The model considers exchanges that involve a presentation without an acceptance to be *ungrounded*. Discourse contributions take place at two layers: *intention* and *conversation*. At the intention layer, the system plans communication intentions based on analyses of previous discourse and the robot's control system. These intentions can be *self-* or *other-motivated* for each agent. The conversation layer involves the articulation of communication intentions through verbal and nonverbal behaviors. The two layers form an *interaction unit (IU)* in the model. The model determines whether an IU is presentation or acceptance and whether it is grounded or ungrounded by assessing whether it satisfies joint intentions of the agents. Figure 71.12 illustrates how an other-motivated exchange is assessed by the model to determine whether the exchange is a presentation or an acceptance.

Models of Situated Human–Robot Dialog

The models and systems described above consider task-based and communicative exchanges in HRI as a dialog and extend models of spoken dialog to accommodate requirements that are specific to HRI, such as task-management, mixed-initiative dialog management, and physically situated referencing. Research in cognitive HRI has also explored the development of dialog systems that explicitly integrate these mechanisms into dialog modeling and the development of specific models and mechanisms for these requirements.

An example of dialog systems that are specifically developed for situated human–robot dialog is the pattern-based mixed-initiative (PaMini) HRI framework [71.140]. This framework extends spoken dialog systems with two key components: a task-state protocol and interaction patterns. The task-state protocol component explicitly defines *tasks* that either the robot's perceptual or control subsystems can perform. A task is defined as an execution state and preconditions for execution. The task-state protocol specifies task states and transitions among them to support coordination. The interaction patterns component provides high-level representations of recurring dialog structures such as a *clarification*. A comparison of most commonly used spoken dialog systems and the PaMini framework in the context of a human–robot situated learning scenario is provided by Peltason and Wrede [71.141].

Another example is the Robot Behavior Toolkit developed by Huang and Mutlu [71.3], which supports

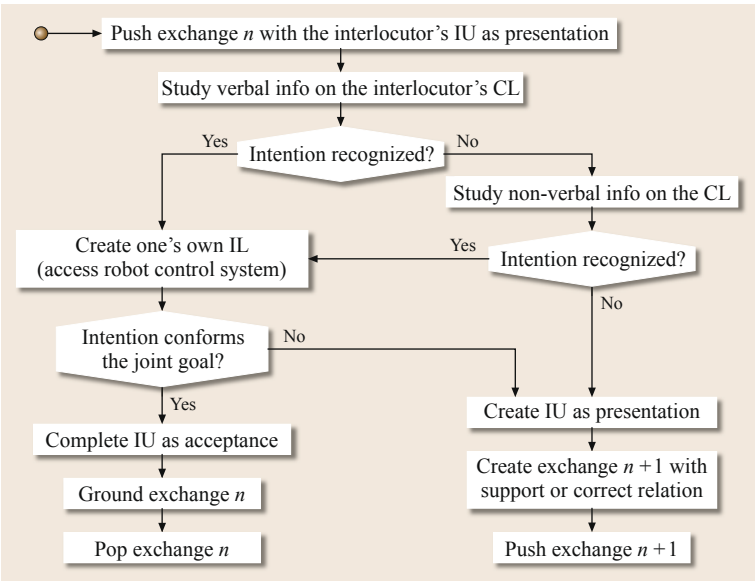

Fig. 71.12 The model evaluates an exchange provided by the interaction partner to determine its *presentation* or *acceptance* status and determine an appropriate action (after [71.138])

situated human–robot dialog by integrating nonverbal cues for task-based referential communication and conversation into the robot’s speech. This system uses a *repository* of specifications of situated communication cues based on models of human interactions and an *activity* model (described in more detail below) that specifies the joint human–robot activity including the agents, task context, shared task goals, and expected

task outcomes to integrate the situated communication cues that are expected to support these outcomes into the robot’s speech. Figure 71.13 displays an example behavior generated by the Toolkit in a collaborative manipulation task. An evaluation of their system showed that interactions in which the robot displayed these situated communication cues as directed by the system more effectively supported desired task outcomes compared with baseline interactions (VIDEO 128).

Research in cognitive HRI has also explored the development of models for specific communication and coordination mechanisms in situated interaction, such as perspective-taking, spatial referencing, reference resolution, and joint attention (VIDEO 129).

Perspective-Taking. A core process in situated interaction toward establishing common ground is *perspective-taking* [71.142]. Research in social cognition has shown that the ability to take another’s perspective and share common ground significantly improves collaborative performance in human teams [71.143]. Research in HRI has also explored how robots might employ this core mechanism to establish common ground with their users in situated interactions and has proposed several models that supported perspective taking.

Trafton et al. [71.144] studied interactions among astronauts in a naturalistic collaborative assembly task and found that a quarter of the utterances in the data involved taking the perspective of another and that participants frequently switched among egocentric, exocentric, addressee-centered, and object-centered perspectives. Based on their results, they developed a cog-

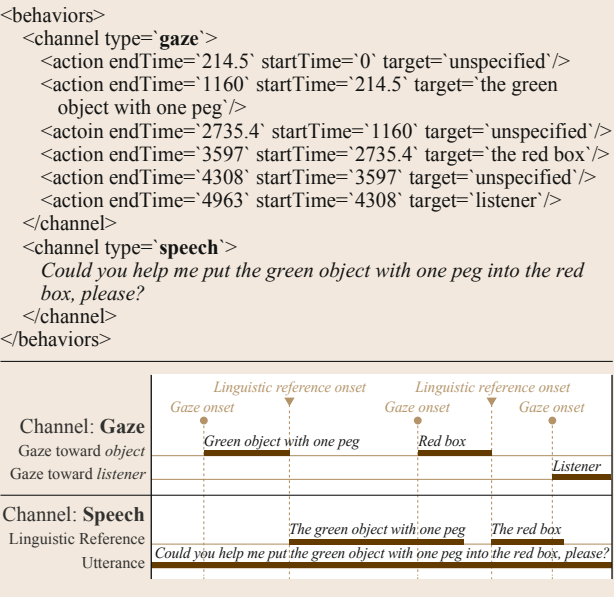

Fig. 71.13 The robot behavior toolkit uses specifications from a repository and a model of the joint activity to integrate effective multimodal task-related dialog behaviors (after [71.3])

nitive model of perspective taking that allowed the robot to maintain multiple perspectives – or *alternative worlds* – at once and explore propositions about these worlds, such as the perspective of an interaction partner. This exploration allowed the robot to make inferences about the perspective of its partner by simulating this alternative world and act on the world from this perspective. The following sequences of actions illustrate the simulations that the robot might carry out based on the command *go to the cone* (adapted from Trafton et al. [71.2]). Underlined text describes components of the system implementation:

Simulate current real world (i. e., perceive it)

Perception specialist notices the existence and location of *person*, *cone₁*, *cone₂*, and *obstacle*
Language specialist hears *Coyote*, *go to the cone* and infers that there is an object, *C*, that is a cone and that the *person* wants it to go to
Identity hypothesis specialist infers that *C* can be identical to *cone₁* or *cone₂*
 $C = \text{cone}_1, C = \text{cone}_2$
Identity constraint specialist notices a contradiction
 This contradiction triggers the counterfactual simulation strategy

Simulate the world where $C = \text{cone}_1$

Because in this world *person* has referred to *cone₁*, the perspective-simulation strategy is triggered

Simulate the world where $C = \text{cone}_1$ and *robot* = *person*

The spatial reasoning perspective indicates that *cone₁* does not exist in this world because *person* cannot see it

Thus, $C \neq \text{cone}_1$

Simulate the world where $C = \text{cone}_2$

Because in this world *person* has referred to *cone₂*, the perspective-simulation strategy is triggered

Simulate the world where $C = \text{cone}_2$ and *Robot* = *Person*

Because *cone₂* is visible in this world, there is no contradiction in this world

Infer that $C = \text{cone}_2$ (i. e., *the cone* refers to *cone₂*)

Following a *counterfactual simulation strategy* provides the robot with the ability to make inferences about situated actions across alternative scenarios with alternative physical (e.g., whether or not an object is present) and cognitive (e.g., whether or not the object is visible to the human counterpart) characteristics and determine appropriate next actions, such as carrying out a request or seeking clarification from its human counterpart.

Figure 71.14 illustrates four alternative scenarios with different physical and cognitive properties explored by Trafton et al. [71.144]. In each scenario, the robot assesses these properties to determine its next actions, as illustrated below.

Algorithm 71.1

```

function: Scenario( $n\text{Cones} = 1 \Rightarrow \text{cone}_a$ )
if  $\text{cone}_a = \text{visible}_{\text{robot}} \wedge \text{cone}_a = \text{visible}_{\text{human}}$  then
  Go to  $\text{cone}_a$ 
end if
function: Scenario( $n\text{Cones} = 2 \Rightarrow \text{cone}_a, \text{cone}_b$ )
if  $\text{cone}_a, \text{cone}_b = \text{visible}_{\text{robot}} \wedge \text{cone}_a = \text{visible}_{\text{human}}$  then
  Go to  $\text{cone}_a$ 
end if
function: (Scenario( $n\text{Cones} = 1 \Rightarrow \text{cone}_a$ ))
if  $\text{cone}_a, \text{cone}_b \neq \text{visible}_{\text{robot}} \wedge \text{cone}_a = \text{visible}_{\text{human}}$  then
  Check hidden location
end if
function: Scenario( $n\text{Cones} = 2 \Rightarrow \text{cone}_a, \text{cone}_b$ )
if  $\text{cone}_a, \text{cone}_b = \text{visible}_{\text{robot}} \wedge \text{cone}_a,$ 
    $\text{cone}_b = \text{visible}_{\text{human}}$ 
then
  Request clarification
end if
  
```

Berlin et al. [71.145] developed a similar model that enabled the robot to understand its environment from the perspective of an interaction partner by maintaining

Fig.71.14a–d The alternative scenarios considered by the system in which the robot and its human counterpart are in a room with several objects and possible occlusions from the perspectives of the robot or the human (after [71.144])

separate and potentially different sets of beliefs in its belief system for itself and for its interaction partner. To construct a model of the beliefs of its interaction partner, the robot employed the same mechanisms it used to model its own beliefs but transformed the data it perceived from the world to match the reference frame of its interaction partner. These two sets of beliefs were maintained separately so that the robot can compare differences between its beliefs and its interaction partner's beliefs and plan actions in order to establish common ground or identify discrepancies in its learning in the context of task learning. Figure 71.15 illustrates parallel beliefs maintained by the robot in a button-pressing task.

Spatial Referencing. Moratz et al. [71.146] proposed a cognitive model of spatial reference that represented different kinds of spatial reference systems and allowed the robot to interpret instructions from an interaction partner. This model mapped the locations of all objects as projections on a plan view, considering the robot's point of view as *origin* and the location of the object that will be used as *relatum* to determine the reference axis. This axis enabled the robot to interpret directions such as *left of*, *right of*, *in front of*, and *to the back* in relation to the relatum, providing the robot the ability to interpret natural language references to objects in the environment.

Reference Resolution. Ros et al. [71.147] extended these approaches to develop a model that enabled the robot to clarify references made by its interaction partner. This model employed several mechanisms including visual perspective taking, spatial perspective taking, symbolic location descriptors, and feature descriptors to determine whether it needed any clarification on its interaction partner's references. The visual perspective taking mechanism allowed the robot to determine whether or not objects in the environment were in its interaction partner's focus of attention (FOA), in its part-

ner's field of view (FOV), or out of its partner's field of view (OOF). The spatial perspective taking mechanism maintained egocentric and addressee-centered perspectives to determine ambiguities in object references. The system also included symbolic location descriptions such as *is in*, *is on*, and *is next to* to determine spatial relationships between objects and the environment. Finally, the robot used feature descriptors such as color and shape to identify ambiguities in the references of its interaction partner. Once the robot determined the need clarification in its partner's references, it used an ontology-based clarification algorithm to ask questions to its partner about the object of reference.

Joint Attention. Another key mechanism in situated interaction is *joint attention* – the ability to use non-verbal cues, such as gaze and pointing, to establish common ground on what referents in the environment are under consideration in the dialogue [71.149]. Scassellati [71.99] proposed a task-based decomposition of joint attention skills, including mutual gaze, gaze following, imperative pointing, and declarative pointing, and implemented these skills in a robot as stages for establishing joint attention with a human counterpart. The mutual gaze skill provided the robot with the ability to recognize and maintain eye contact with its interaction partner. At the gaze following stage, the robot followed the eyes of its partner to direct its attention to the object of its partner's attention. Imperative pointing involved pointing at an object that is out of reach in order to request the object. Finally, the declarative pointing stage involved extending an arm and index finger to draw attention to an object that is out of reach without necessarily requesting the object.

Connection Events. Rich et al. [71.150] argued that mechanisms such as joint attention serve as *connection events* in situated dialog and establish and maintain engagement among interaction partners. From data on human interactions, they identified a set of key connec-

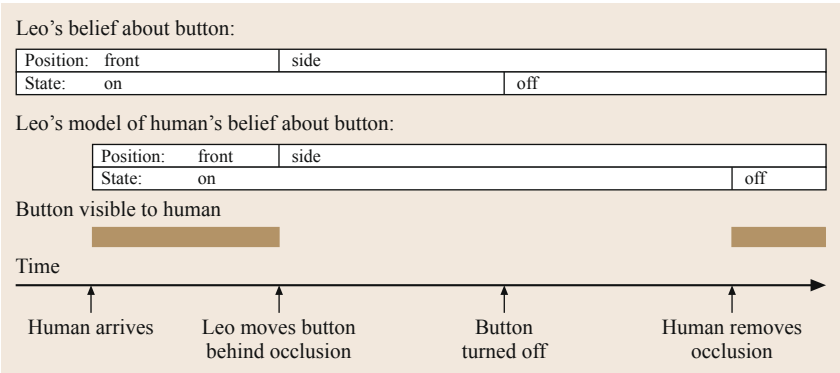

Fig. 71.15 In the system proposed by Berlin et al. [71.145], the robot maintains a parallel beliefs for itself and for its human counterpart for the task and updates its beliefs based on sensory input and those of the user based on the user's awareness (after [71.145])

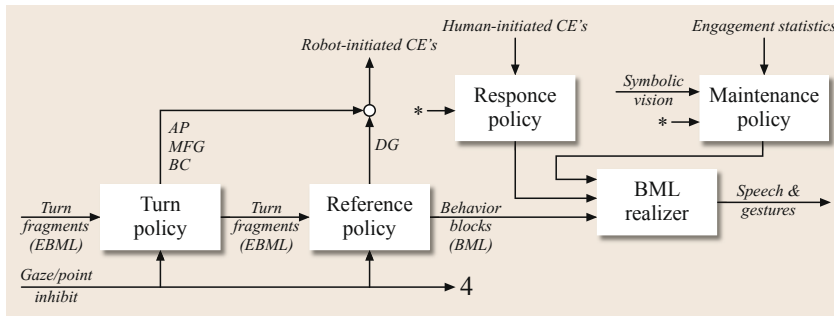

Fig. 71.16 The policy components, the BML realizer, and the generated connection events for the robot in the engagement generator module (after [71.148])

tion events, including mutual gaze, directed gaze, adjacency pairs, and backchannels, and developed a system that recognized these events in human counterparts and generated them for a robot (see Rich et al. [71.150] for details on the recognizer and Holroyd et al. [71.148] for details on generation). The recognizer module included dedicated recognizers for each type of connection event and an estimator for engagement levels for the robot's human counterpart, while the generation module included four policy components and a behavior mark-up language (BML) realizer for generating robot behaviors toward establishing and maintaining engagement. The components of this engagement generator are illustrated in Fig. 71.16.

71.3.2 Simulation-Theoretic Models

Research in cognitive HRI has also been inspired by neurocognitive mechanisms in developing models of human–robot joint activity, building particularly on *simulation theory*, which suggests that people (and primates) represent other people's mental states by adopting their perspective, specifically by tracking or matching their states with resonant states of their own [71.151]. This simulation-theoretic approach led to several models of robot behavior and human–robot joint action that involve the robot imitating or simulating the behaviors of its interaction partner in order to learn from or make inferences about its partner's goals.

As an example of this approach, Bicho et al. [71.152] proposed a model for action preparation and decision-making in cooperative human–robot tasks that is inspired by the finding that action observation elicits an automatic activation of motor representations associated with the execution of the observed action. This *motor-resonance mechanism* allows people to internally simulate action consequences using their own motor repertoire and predict the consequences of action of others. In the proposed model, a perception–action linkage enables efficient coordination of actions and decisions between the agents in a human–robot joint action task.

The model integrates a mapping between observed actions and complementary actions in memory, while taking into account the inferred goals of the actions of the interaction partner, contextual cues, and shared task knowledge.

Building on simulation theory, Gray et al. [71.153] proposed a similar system in which the robot parses user actions and matches the user's movements to movements in its own repertoire toward making inferences about the user's goals and perform a task-level simulation (Fig. 71.17). This simulation allows the robot to determine the preconditions of the schemas that represent the task and track its human partner's progress over the course of the task in order to anticipate its partner's needs and offer relevant help accordingly. The simulation also provided the robot with the ability to make inferences on the beliefs of its partner and simulate its partner's perspective in a fashion similar to the perspective-taking mechanisms proposed by Trafton et al. [71.144] and Berlin et al. [71.145] (VIDEO 130).

Aspects of the simulation-theoretic approach explicitly taken in these examples can also be seen in other control architectures developed for HRI. Nicolescu and Mataric [71.154] proposed a control architecture that unifies perception and action to achieve *action-based*

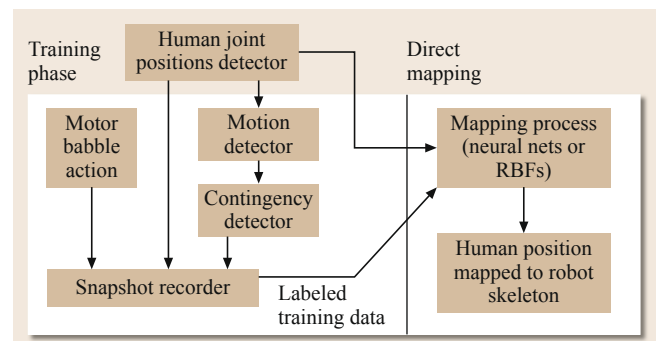

Fig. 71.17 The mapping of perceived human actions onto the robot's body in order to make comparisons and task-level inferences (after [71.153])

interaction. In this architecture, behaviors are built from *perceptual* and *active* components. Perceptual components allow the robot to link its observations and actions and thus to learn to perform a task from the experiences it gains from its interactions with people. Active components enable task-based behaviors that also serve as implicit communication rather than explicit behaviors such as speech and gestures. Behavior representation in the architecture captures two types of behaviors: *abstract* and *primitive*. Abstract behaviors are explicit specifications of the behaviors' activation conditions (preconditions), goals in the form of abstracted environmental states, and effects (postconditions), while primitive behaviors are those that the robot performs to achieve these effects. By linking perceptions and actions, the robot learns what actions of its own might achieve the same observed effects.

71.3.3 Intention- and Activity-Based Models

The models and systems described above are concerned primarily with establishing and maintaining common ground and coordinating actions in task-based interactions using dialog- and simulation-theoretic approaches with limited consideration of the broader context of these interactions as complex activities involving multiple agents with common goals and commitments to these goals. A number of models and systems sought to address this limitation, building on models and theories of human joint activity such as joint intention theory [71.139] and activity theory [71.7].

Building on joint intention theory, Breazeal et al. [71.155] proposed a model of human-robot collaboration that involved dynamically meshing subplans into joint activity toward achieving common goals of the human-robot team. In this model, task and goal representations have a goal-centric view, employing an action-tuple data structure that captures preconditions, executables, until-conditions, and goals. Tasks are represented in a hierarchical structure of actions and recursively defined subtasks. Goals are also represented hierarchically as overall intent rather than a chain of low-level goals. The implemented joint intention model dynamically assigns tasks to members of the human-robot team. These intentions are derived based on the robot's actions and abilities, the actions of the human partner, the robot's understanding of the common goal of the team, and its assessment of the current task state. At every stage of the interaction, the robot negotiates who should complete the task. Action at these points might look like turn-taking or simultaneous action (the robot and the human working on different parts of the task).

Alami et al. [71.156, 157] similarly built on joint intention theory to propose a human-robot decision framework in which team members are committed to a *joint persistent goal* and follow cooperation schemes to contribute toward achieving this goal. The framework involves a goal planner called *the agenda* for the robot and human collaborators to pursue, a proxy representation of the human in the robot called *Interaction Agents (IAA)*, *task delegates* that monitor and control the task commitment of the human or the robot for each active, inactive, or suspended goal, and a *robot supervision kernel* that monitors and controls robot activities. For each new active goal, the Robot Supervision Kernel creates a Task Delegate, selects or elaborates a plan, and allocates the roles of each team member.

Fong et al. [71.1] proposed a similar system called the *HRI operating system (HRI/OS)* to support human-robot teamwork. The system involves a task manager, resource manager, interaction manager, spatial reasoning agent, context manager, human and robot agents, and an open agent architecture (OAA) facilitator. The task manager decomposes the overall goal of the system into high-level tasks and assigns to humans or robots for execution. The manager relies on the agents to complete the low-level steps of the tasks. It communicates with the Resource Manager to find an agent capable of performing the work. Resource manager processes all agent requests, prioritizing the list of agents to be consulted when a task needs to be performed. Interaction manager coordinates dialog-based communication between agents. Context manager keeps track of everything that occurs while the system is running including task status and execution, agent activities, agent dialogue, etc. Spatial reasoning agent (SRA) is used to resolve spatial ambiguities in human-robot dialog through mechanisms such as perspective taking and frames of reference, resolving ambiguities among as ego-, addressee-, object-, and exo-centric references. To do this, SRA transforms the spatial dialog into a geometric reference and perform a *mental simulation* of the interaction to explore how ambiguities might be resolved through multiple references. Finally, the OS includes a software representation of the human – a human proxy agent that represents user capabilities and accepts task assignments in the way that robot agents do. These proxies represent task capabilities, including domains of expertise, and provide health monitoring feedback.

Huang and Mutlu [71.3] built on an alternative model of human activity – activity theory [71.7] – to develop a model of human-robot joint activity. Their model builds on five key constructs from activity theory including consciousness, object-orientedness, hierarchical structure, internationalization and external-

ization, and mediation. The *consciousness* construct pertains to attention, intention, memory, reasoning, and speech and includes specific representations for attention and intention. The *object-orientedness* construct describes material artifacts, plans of action, or common ideas to be shared by the members of the joint activity. Following the *hierarchical structure* construct, the model organizes joint activity into three layers: activity, action, and operation. An activity consists of a series of actions that share the same goal, and each action has a defined goal and a chain of operations that are regular routines performed under a set of conditions. *Internalization and externalization* describes cognitive processes; internalization involves transforming external actions or perceptions into mental processes, while externalization is the process of manifesting mental processes in external actions. Finally, the *mediation* construct defines several external and internal tools, such as physical artifacts that might be used in an activity and cultural knowledge or social experience that an individual might have acquired, as mediators of human–robot joint activity. These constructs and their corresponding system elements allow the construction of and planning for joint human–robot activities. For each activity, a *motive* governs actions. Each action, by achieving its corresponding goal, helps to fulfill the motive of the activity. Each action may have several *operations* that are constrained by a set of conditions and that can be executed only when all the conditions are met. Actions have predefined *outcomes*, which specify the orientation of an action. Figure 71.18 shows the XML (extensible markup language) representation of a model of a collaborative manipulation task.

71.3.4 Models for Action Planning

The models described above primarily enable communication and coordination between humans and robots toward planning and carrying out joint tasks. In order to successfully contribute to these tasks, robots also need models for planning their actions in a dynamic physical and cognitive environment. Research in cognitive HRI seeks to develop models for *action planning* that help robots estimate the actions that they have to take in order to achieve task goals and learn the parameters of the tasks space. The paragraphs below review research in two common approaches to building such models: *decision-theoretic models* and *model learning*.

Decision–Theoretic Models

One of the simplest approaches to control and decision-making in HRI is to define the interaction as a decision-theoretic planning problem, such as a Markov decision process (MDP). Formally, an MDP consists of the n -

tuple $\{S, A, T, R, \gamma\}$. The set S is a set of states, which in the HRI setting typically correspond to the combination of state variables, such as the robot state and the desired outcome of the interaction. For example, if the interaction model allows a human partner to instruct the robot to move to different locations in the environment, one state variable may correspond to different current locations of the robot and another state variable may correspond to the goal states intended by the human partner. The full state space S is given by the combination of possible values for the different state variables.

The action set A represents actions that the robot may take. The actions may include asking a question, performing some physical movement, or even doing nothing. Each action has a cost R depending on the current state, which rewards the robot for performing useful actions, and penalizes the robot for taking actions that either make no immediate progress toward the specified goal (typically a small penalty) or completely unhelpful (a large penalty).

Lastly, the transition function T provides a notion of the dynamics of the environment in terms of how the state changes as robot takes actions, and especially how a human partner's state variables may change as the robot takes actions. The transition function $T(s'|s, a)$ places a probability distribution over the states to which the user in state s may transit if the robot takes action a . The MDP formulation is very appealing, because there exist efficient techniques for solving for interaction policies. Once the policy is computed, the interaction can be managed simply by querying the policy for the

```
<Activity id='1'>

    <Description>
      Instruct User1 to categorize object
    </Description>
    <Operation type='utterance'>
      <Condition>present(User1)</Condition>
      <Condition>
        known(the blue object with two pegs)
      </Condition>
      <Condition> known(the blue box)</Condition>
      <Info turn='end'>
        Could you help me put the blue object with
        two pegs into the blue box, please?
      </Info>
    </Operation>
  ...
</Action>
</Activity>
```

Fig. 71.18 The XML representation of the activity-theory-based model for a collaborative manipulation task (after [71.3])

appropriate action in response to the current state of the robot and the human partner.

A limitation of the MDP approach is that some of the state variables may not be directly observable, in particular the state variables corresponding to human intentional states, such as intended goal locations of the robot. The values of the state variables must be inferred from observations, such as speech acts performed by the human partner, which are inherently noisy. For example, the system may hear the words *coffee machine* when the user asks the robot to go to *copy machine*. While speech recognition errors may be mitigated to some extent by asking the user to use only acoustically distinct keywords when speaking to the system, a system that does not model the likelihood of recognition errors and act accordingly will be brittle; a robust system must be able to infer user intent under uncertainty.

The observations are rarely sufficient to uniquely determine the current state, but more commonly are used to compute a *belief*, or probability distribution over dialog states. If the agent takes some action a and hears observation o from an initial belief b , it can easily update its belief using Bayes rule

$$b^{a,o}(s) = \frac{\Omega(o|s', a) \sum_{s \in S} T(s'|s, a)b(s)}{\sum_{\sigma \in S} \Omega(o|\sigma, a) \sum_{s \in S} T(\sigma|s, a)b(s)} . \quad (71.1)$$

This probability distribution will evolve as the dialog manager asks clarification questions and receives responses. In Fig. 71.19, we show a cartoon of a simple dialog model. Initially, we model the user as being in a *start* state. Then, at some point in time, the user speaks to the robot to indicate that he or she wants it to perform a task. We denote this step by the set of vertical stack of nodes in the center of the model. Each node represents a different task. The dialog manager must now interact with the user to determine what is wanted. Once the task is successfully completed, the user transitions to the right-most *end* node, in which he or she again does not desire anything from the robot. We note that it can be easily augmented to handle more complex scenarios. For example, by including the time of day as part of the state, we can model the fact that the user may usually wish to go to certain locations in the morning and other locations in the afternoon.

Intuitively, we can see how the belief can be used to select an appropriate action. For example, if the dialog manager believes that the user may wish to go to either the coffee machine or the copy machine (but not the printer), then it may ask the user for clarification before commanding the wheelchair to one of the locations. More formally, we call the mapping from beliefs

to actions a policy. We represent this mapping using the concept of a value function $V(b)$. The value of a belief is defined to be the expected long-term reward the dialog manager will receive if it starts a user interaction in belief b . The optimal value function is piecewise-linear and convex, so we represent V with the vectors V_i ; $V(b) = \max_i V_i \cdot b$. The optimal value function satisfies the Bellman equation [71.158]

$$V(b) = \max_{a \in A} Q(b, a) ,$$

$$Q(b, a) = R(b, a) + \gamma \sum_{o \in O} \Omega(o|b, a) V(b_a^o) , \quad (71.2)$$

where $Q(b, a)$ represents the expected reward for starting in belief b , performing action a , and then acting optimally. The belief b_a^o is b after a Bayesian update of b using (71.1), and $\Omega(o|b, a)$, the probability of seeing o after performing a in belief b ($\sum_{s \in S} \Omega(o|s, a)b(s)$).

There are also non-Bayesian approaches for acting in uncertain environments. Many interaction systems provide the dialog manager with a set of rules to follow given particular outputs from a speech recognition system. The drawback to rule-based systems is that they often have difficulty managing the many uncertainties that stem from noisy speech recognition or linguistic ambiguities. The ability to manage the trade-off between gathering additional information and servicing a user's request have made partially observable Markov decision process (POMDP) planners particularly useful in dialog management; applications include a Nursebot robot, designed to interact with the elderly in nursing homes [71.159], a vision-based system that aids Alzheimer's patients with basic tasks such as hand-washing [71.160], an automated tele-

Fig. 71.19 A toy example of a dialog POMDP. The nodes in the graph are different states of the dialog (i. e., user requests). Solid lines indicate likely transitions; we assume that the user is unlikely to change their request before their original request is fulfilled. The system automatically resets once we reach the end state

phone operator [71.161], and a tourist information kiosk [71.162].

Beyond the initial formulations of cognitive HRI as a decision-theoretic problem, there have been a number of algorithmic improvements that increase the domains of applicability of this approach. For example, the conventional MDP and POMDP algorithms have typically assumed that each observation and action takes approximately the same amount of time, which can lead to an implicit bias toward longer actions. Representing time explicitly leads to computational intractability, but Broz et al. [71.163] demonstrated that the similar states that vary only by the time-index can be aggregated, leading to reduced-order models that can be solved very efficiently. Similarly, Doshi and Roy [71.164] showed that symmetries in human intentional states could be exploited to dramatically reduce the size of the planning problem, also leading to very efficient solutions. Most recently, again in the non-Bayesian line, Wilcox et al. have shown that the temporal dynamics of task-based HRI can be formulated as a scheduling problem [71.165].

Model Learning

The behavior of the dialog manager derived from solving (71.2) depends critically on accurate choices of the transition probabilities, observation probabilities, and the reward. For example, the observation parameters affect how the system associates particular keywords with particular requests. Similarly, the reward function affects how aggressive the dialog manager will be in assuming that it understands a user's request, given limited and noisy information. An incorrect specification of the dialog model may lead to behavior that is either overly optimistic or conservative, depending on how accurately the model captures the user's expectations on the interaction.

A common approach in other domains is to collect data using a fixed policy, typically referred to as system identification. In HRI, this is easiest to perform using so-called *Wizard of Oz* studies where a human experimenter executes the policy unseen to generate data or evaluate a policy. Prommer et al. [71.166] showed that Wizard-of-Oz studies could be used effectively not only to learn model parameters for an MDP dialog model, but also to learn an effective policy.

At the same time, learning all the parameters required to specify a rich dialog model can require a prohibitively large amount of data. While the model parameters may be difficult to specify exactly, either by hand or from data, we can often provide the dialog manager with an initial estimate of the model parameters that will generate a reasonable policy that can be executed while the model is improved. For example, even

though we may not be able to attach an exact numerical value to driving a wheelchair user to the wrong location, we can at least specify that this behavior is undesirable. Similarly, we can specify that the exact numerical value is initially uncertain. As data about model parameters accumulate, the parameter estimates should converge to the correct underlying model with a corresponding reduction in uncertainty.

Figure 71.20a depicts the conventional model, where the arrows in the graph show which parts of the model affect each other from time t to $t + 1$. Although the variables below the *hidden* line in Fig. 71.20a are not directly observed by the dialog manager, the parameters defining the model (i.e., the parameters in the function giving the next state) are fixed and known

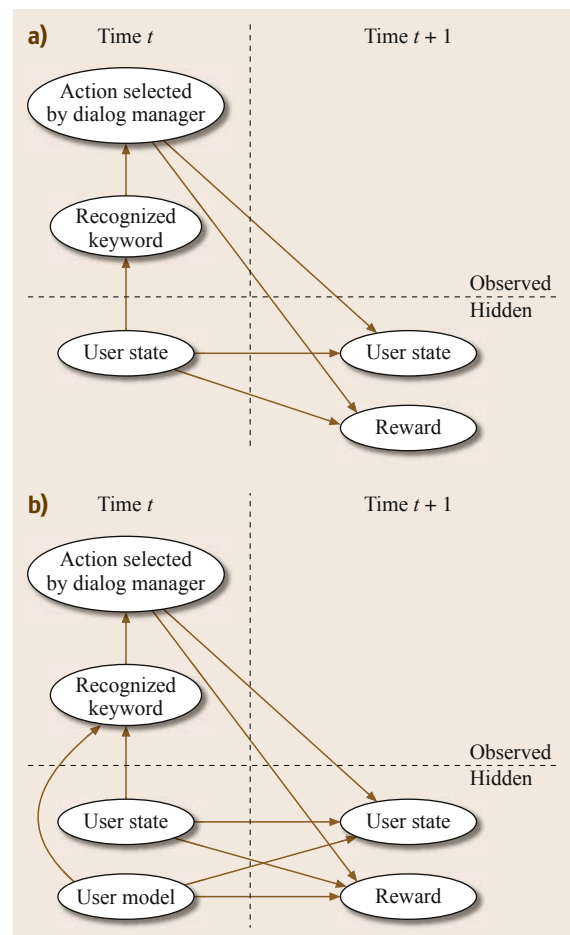

Fig. 71.20 (a) The standard POMDP model. (b) The extended POMDP model. In both cases, the arrows show which parts of the model are affected by each other from time t to $t + 1$. Not drawn are the dependencies from time $t + 1$ onward, such as the user state and user model's effect on the recognized keyword at time $t + 1$

a priori. For instance, the reward at time t is a function of the state at the previous time and the action chosen by the dialog manager.

If the model parameters are not known a priori because the model is uncertain – for example, how much reward is received by the agent given the previous state and the action selected – then the concept of the belief can be extended to also include the agent's uncertainty over possible models. In this new representation, which we call the *model-uncertainty POMDP*, both the user's request and the model parameters are hidden. Figure 71.20b shows this extended model, in which the reward at time t is still a function of the state at the previous time and the action chosen by the dialog manager, but the parameters are not known a priori and are therefore hidden model variables that must be estimated along with the user state. The system designer can encode their knowledge of the system in the dialog manager's initial belief over what dialog models it believes are likely – a Bayesian prior over models – and let the agent improve upon this belief with experience.

Poupart et al. treated the unknown MDP parameters as hidden state in a larger POMDP and derived an analytic solution (based on [71.167]) for a policy that will trade optimally between learning the MDP and maximizing reward. Unfortunately, these techniques did not extend tractably to the model-uncertainty POMDP, which is continuous in both the POMDP parameters (like the MDP) and the belief state (unlike the MDP). Doshi and Roy [71.168, 169] provided an approximate, Bayes risk action selection criterion that allows the dialog manager to function in this complex space of dialog models. This approach was applied to the intelligent wheelchair assistant shown in Fig. 71.21. Their goal was to design an adaptable HRI system, or dialog manager, that allows both the user of the wheelchair and a caregiver to give natural instructions to the wheelchair, as well as ask the wheelchair computer for general information that may be relevant to the user's daily life.

In contrast to the Bayesian approach, Cakmak and Thomaz [71.170] pursued an active learning approach and identified three types of queries that a robot could generate while learning a new task (VIDEO 237). While this result does not provide a comparison to an approach embedded in an ongoing dialogue, their results do provide guidelines for model designers.

71.3.5 Cognitive Models of Robot Control

A final line of research in cognitive HRI seeks to achieve greater task efficiency in human–robot teams, thus addressing common problems between opera-

tors and robots such as those identified by Burke et al. [71.133] and Stubbs et al. [71.134], by developing models and control interfaces that exploit mechanisms of human cognition such as working memory and mental models [71.171, 172]. This research includes formalisms such as *neglect time*, the amount of time that an operator can neglect a robot before the robot's performance drops below a certain threshold [71.171], and *fan out*, a measure of how many robots an operator can effectively manage in a human–robot team [71.172]. Such formalisms inform the development of guidelines for designing effective control mechanisms such as the following principles proposed by Goodrich and Olsen [71.171]:

1. *Implicitly switch interfaces and autonomy modes.* Context determines the mode of use. For instance, the user starts using a joystick and the interaction modality automatically switches, rather than the user explicitly selecting a modality.
2. *Let the robot use natural human cues.* The robot uses the cues to provide feedback and present information that the human uses to provide the commands or present information to the robot.
3. *Manipulate the world instead of the robot.* Control interfaces integrate knowledge about the task and the world to minimize low-level control of the robot and maintaining of a mental model of the robot's functioning.
4. *Manipulate the relationship between the robot and world.* Control interfaces provide real-world

Fig. 71.21 Our dialog manager allows for more natural human communication with a robotic wheelchair (after [71.168, 169])

representations for control to minimize low-level control.

5. *Let people manipulate presented information.* Interfaces present information in a way that represents the real world and allows users to provide input directly into the representation rather than translating information readings to a different modality or representation.
6. *Externalize memory.* Different types of information are integrated into a single representation to reduce the working memory load for the user.
7. *Help people manage attention.* The robot provides appropriate indicators to capture the attention of the operator.
8. *Learn.* Control mechanisms adapt system activity to the user's mental models.

71.4 Conclusion and Further Reading

This chapter presented an overview of research in cognitive human–robot interaction, the area of research concerned with modeling human, robot, or joint human–robot cognitive processes in the context of HRI. This research seeks to gain a better understanding of people's interaction with robots and build robotic systems with the necessary cognitive mechanisms to communicate and collaborate with their human counterparts. Three key themes fall within this research area. The first theme seeks to build a better understanding of human cognition in HRI; specifically, people's mental models of robots as ontological entities, social cognition of robot behaviors, and the use of robots as experimental platforms to study cognitive development in humans. The second theme includes research that seeks to build models for simulating human cognition in robots, gaining cognitive capabilities through imitation and interaction with the physical environment, and mapping aspects of interaction, such as commands from or references by human counterparts to objects in the environment. The final theme seeks to build models that support human–robot joint activity, including dialog-, simulation-theoretic-, joint-intention-, activity- and action-planning-based models that enable robots to reason about the physical and cognitive properties of the environment and the actions of their human counterparts and to plan actions toward achieving communicative or collaborative goals. The common thread among these three themes of research is the consideration of humans and robots as part of a cognitive

system in which cognitive processes – natural or designed – shape how humans and robots communicate and collaborate.

As an interdisciplinary area of research, cognitive human-robot interaction receives contributions from a diverse set of research fields including robotics, cognitive science, social psychology, communication studies, and science and technology studies. Further reading on the topic is also available in a diverse set of venues such as:

72. Social Robotics

Cynthia Breazeal, Kerstin Dautenhahn, Takayuki Kanda

This chapter surveys some of the principal research trends in Social Robotics and its application to human–robot interaction (HRI). Social (or Socialable) robots are designed to interact with people in a natural, interpersonal manner – often to achieve positive outcomes in diverse applications such as education, health, quality of life, entertainment, communication, and tasks requiring collaborative teamwork. The long-term goal of creating social robots that are competent and capable partners for people is quite a challenging task. They will need to be able to communicate naturally with people using both verbal and nonverbal signals. They will need to engage us not only on a cognitive level, but on an emotional level as well in order to provide effective social and task-related support to people. They will need a wide range of social-cognitive skills and a theory of other minds to understand human behavior, and to be intuitively understood by people. A deep understanding of human intelligence and behavior across multiple dimensions (i. e., cognitive, affective, physical, social, etc.) is necessary in order to design robots that can successfully play a beneficial role in the daily lives of people. This requires a multidisciplinary approach where the design of social robot technologies and methodologies are informed by robotics, artificial intelligence, psychology, neuroscience, human factors, design, anthropology, and more.

72.1 Overview

The way a person interacts with a social robot (or sociable robot) is quite different from interacting with the majority of autonomous mobile robots today. Modern autonomous robots are generally viewed as tools that human specialists use to perform hazardous tasks in remote environments (i. e., sweeping minefields, inspecting oil wells, mapping mines, etc.). In dramatic contrast, social (or sociable) robots are designed to engage people in an interpersonal manner, often as partners, in order to achieve positive outcomes in domains such as education, therapy, or health, or task-related goals in areas such as coordinated teamwork for manufacturing, search and rescue, domestic chores, and more.

The development of socially intelligent and socially skillful robots drives research to develop autonomous or semiautonomous robots that are natural and intuitive for the general public to interact with, communicate with, work with as partners, and teach new capabilities. *Dautenhahn*’s work is among the earliest in thinking about robots with interpersonal social intelligence where relationships between specific individuals are important [72.1, 2]. These early works pose the question:

What are the common social mechanisms of communication and understanding that can produce efficient, enjoyable, natural and meaningful interactions between humans and robots?

Promisingly, there have been initial and ongoing strides in all of these areas ([72.3–11], etc.). In addition, this domain motivates new questions for robotics researchers, such as how to design for a successful long-term relationship where the robot remains appealing and provides consistent benefit to people over weeks, months, and even years. The benefit that social robots provide people extends far beyond strict task-performing utility to include educational (Chap. 79), health and therapeutic (Chap. 64), domestic (Chap. 65), social and emotional goals (e.g., entertainment, companionship, communication, etc.), and more.

We begin this chapter with a brief overview of a wide assortment of embodiments of socially interactive robots that have been developed around the world (Sect. 72.2). We follow with selected topics that highlight some of the representative research themes: social-emotional intelligence and emotion-based interaction (Sect. 72.3), and social-cognitive skills (Sect. 72.4). Human social responses to robots(Sect. 72.5), verbal and non-verbal communication (Sect. 72.6), long-term interaction (Sect. 72.7), touch-based interaction (Sect. 72.8), and teamwork with robot partners (Sect. 72.9). We rely on examples from our own research programs to illustrate these trends, while making reference to other excellent works performed in other research labs.

72.2 Social Robot Embodiment

72.2.1 Anthropomorphic Design

Social robots are designed to interact with people in human-centric terms and to operate in human environments alongside people. Many social robots are humanoid or animal-like in form, although this does not have to be the case. A unifying characteristic is that that social robots engage people in an interpersonal manner, communicating and coordinating their behavior with humans through verbal, nonverbal, or affective modalities. People have a strong tendency to anthropomorphize social robots [72.12] and to reason

about their behavior in terms of having their own mental states (e.g., thoughts, intents, beliefs, desires, etc.). Hence, anthropomorphic design principles, spanning from the physical appearance of robots, to how they move and behave, and how they interact with people, are often employed to facilitate interaction and acceptance.

72.2.2 Design Space

The design space of social robotics is quite large. It is important to note that a more human-like design

Fig.72.1a–c Examples of socially interactive humanoid robots: **(a)** Humanoid robots developed at Waseda University from left to right: a flutist robot WF-4RII (after [72.13]), WABIAN-2 (after [72.14]), and WE-4RII (after [72.15]); **(b)** Robovie developed at ATR (Advanced Telecommunications Research Institute, Kyoto) is able to gesture with its arms and give a hug; **(c)** Nexi and Maddox, developed at MIT, are mobile and dexterous social robots used to study collaborative human–robot teamwork (after [72.16])

does not necessarily correlate with a *better* design. One needs to balance the robot design with the task, user, and context [72.17]. As can be seen in the following examples, social robots exploit many different modalities to communicate and express social-emotional behavior. These include whole-body motion, proxemics (i. e., interpersonal distance), gestures, facial expressions, gaze behavior, head orientation, linguistic or emotive vocalization, touch-based communication, and an assortment of display technologies.

For social robots to close the communication loop and coordinate their behavior with people, they must also be able to perceive, interpret, and respond appropriately to verbal and nonverbal cues from humans.  **VIDEO 219** shows dog-inspired robot behaviour to facilitate intention reading by people. Given the richness of human behavior and the complexity of human environments, many social robots are among the most sophisticated, articulate, behaviorally rich, and intelligent robots today.

As shown in Fig. 72.1, a number of socially interactive humanoid robots have been developed (Chap. 65) that can participate in whole body social interaction

with people such as dancing [72.22], walking hand-in-hand [72.23, 24], playing a musical duet [72.13], or transferring skills to unskilled persons [72.25], or collaborating as a team with people in search and retrieve tasks [72.16]. Their arms and hands are designed to exhibit human-like gestures such as pointing, shrugging shoulders, shaking hands, or giving a hug [72.26–28]. Some of them are designed with mechanical faces to communicate with humans via facial expressions [72.18, 20, 29].

Whereas many of these humanoids have a mechanical appearance, android robots are designed to have a very human-like appearance with skin, teeth, hair, and clothes (Fig. 72.2). A design challenge of android robots is to avoid the *uncanny valley* where the appearance and movement of the robot resemble more of an animate corpse than a living human. Designs that fall within the *uncanny valley* elicit a strong negative reaction from people [72.37]. In contrast to trying to look as human-like as possible, there are also more doll-like robots that are intentionally designed to have simplified facial cues and predictable movements to be suitable for therapeutic contexts [72.21].

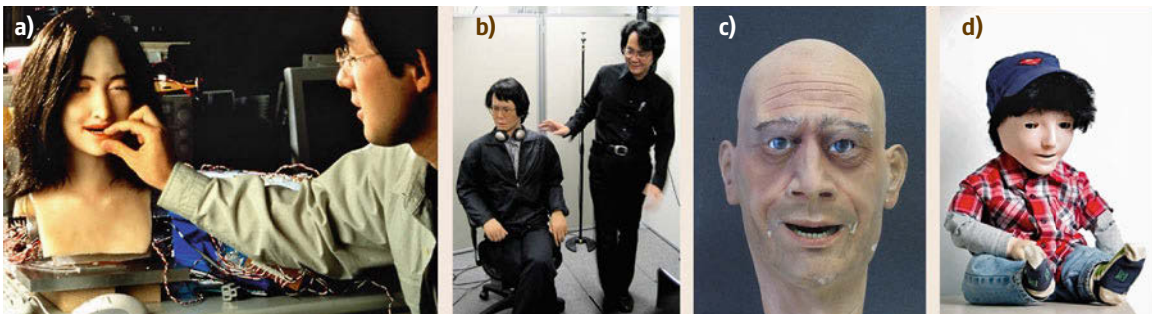

Fig.72.2a–d Some examples of androids: **(a)** One of the earliest face robots developed at the Science University of Tokyo (after [72.18]); **(b)** Geminoid developed at ATR (after [72.19]); **(c)** ROMAN developed at the University of Kaiserslautern (after [72.20]); **(d)** KASPAR developed at the University of Hertfordshire is a child like robot used during therapeutic interventions to help children with autism (after [72.21])

Fig.72.3a–d Examples of social robots inspired by animals with anthropomorphic qualities: (a) AIBO, the robotic dog developed by Sony (after [72.30]), (b) Paro, the therapeutic seal robot developed at AIST (after [72.31]), (c) Mel, the conversational robotic penguin developed at MERL (after [72.32]), and (d) Leonardo developed at the MIT Media Lab (after [72.33])

Fig.72.4a–d Examples of social robots that are neither humanoid nor zoomorphic but capture key social attributes: (a) Kismet (after [72.3]); (b) Keepon (after [72.34]); (c) Pearl (after [72.35]); (d) Valerie (after [72.36])

There are a number of more creature-like social robots that take their aesthetic and behavioral inspiration from animals (Fig. 72.3). Given that people pet and stroke companion animals, touch-based communication has been explored in several of these more animal-inspired robots. Sony's entertainment robot dog, AIBO [72.30, 38], is a well-known commercial example. Other robots in this category have a more organic appearance, such as the therapeutic companion robot seal, Paro [72.31]. Researchers have chosen to design robots with a more fanciful appearance, melding anthropomorphic with animal-like qualities such as Leonardo ([72.32, 33, 39], etc.).

Many social robots are not overtly humanoid or zoomorphic, but still capture key social attributes (Fig. 72.4). For instance, one of the best-known and pioneering social robots Kismet [72.3] developed at the MIT Artificial Intelligence Lab. Kismet had a very expressive mechanical face with anthropomorphic fea-

tures like large blue eyes. Another example is the dancing robot Keepon developed by NiCT (Japan). This small yellow robot has a simplistic face and uses a classic animation technique called *squash and stretch* for expression of the body [72.34].

Many mobile social robots have been fitted with faces to enhance social interaction (Fig. 72.4). Some examples are the eldercare robot, Pearl [72.35], and the robotic receptionist Valerie with a graphical face on a LCD (liquid crystal display) screen [72.36], both developed at Carnegie Mellon University. Other examples are commercial robots like PaPeRo developed by NEC [72.40]. Still, some social robots have no overt social features like faces or eyes, but rely purely on language-based communication. Issues of proxemics on mobile social robots have also been explored such as how a robot should approach a person [72.41], follow a person [72.42], or maintain appropriate interpersonal distance [72.43].

72.3 Social Robots and Social-Emotional Intelligence

Humans are fundamentally emotional beings. Consequently, human communication and social interaction often includes affective or emotive factors. To support the emotional side of human behavior, researchers are exploring affective interaction and communication

between people and robots. To participate in emotion-based interaction, robots must be able to recognize and interpret affective signals from humans, they must possess their own internal models of emotions (often inspired by psychological theories), and they must be able

to communicate this affective state to others. In general, emotional displays can inform the interpretations about an individual's internal states (agreement or disagreement about a belief, valuing a particular outcome, an action tendency to fight, etc.) and therefore help to predict future actions. Emotional displays can evoke emotional responses in others (e.g., displays of distress can elicit feelings if empathy and motivate another to provide social support). Given that social interactions can serve such a broad range of functions, prominent scientists have argued that emotions evolved because they provide an adaptive advantage to social species where individual relationships matter [72.44].

A growing number of socio-emotional robots have been designed to realize such functions to facilitate human-robot interaction. Some of these robots have been designed with emotional responses or emotion-inspired decision making systems in order to entertain AIBO [72.30], QRIO [72.45, 46], conversationally engage with WE-II [72.47], or bond with people [72.48, 49]. Some have investigated the social-communicative aspects of emotions in coordinating behavior and influencing others, e.g., FEELIX [72.50], Kismet [72.3, 51]. Others have explored the functional role of emotion-inspired processing in order to make robots more intelligent, better able to learn, and better adapted to performing tasks in complex environments [72.52]. More recently, researchers have investigated the role of affect in the context of robots that work with people and perform tasks such as search and rescue/retrieve [72.16, 53, 54]. Finally, others model emotions to make robots better able to handle human emotional states, and to motivate people toward more effective interactions in a range of application domains such as education [72.55], coaching [72.56], or therapeutic systems [72.31].

72.3.1 Theories of Emotion

The robot's computational model of emotion determines the robot's affective responses. This can depend on a myriad of interrelated physical, cognitive, and affective factors that continuously modulate and bias one another. These factors arise from the robot's interactions with the external environment as well as its own internal state (i.e., the current emotional state, the cognitive state, goals, motives, physical states, etc.). The emotional model defines the relationship between these factors and mechanisms that result in the observable behavior of the robot. Many of these computational models of emotion are inspired by theories of human emotions. These theoretical models offer insightful constraints that help researchers to derive coherent computational models.

A number of theoretical perspectives have been particularly influential in the development of computational models of emotion. Appraisal theory emphasizes a causal connection between cognition and emotion [72.57]. In appraisal theory, emotion is evoked from patterns of judgments (called appraisal variables) that characterize the personal significance of events (e.g., events and the individual's beliefs, or desires and intentions). An active area of development is in understanding the relationship between appraisal variables and specific emotion labels, or specific behavioral (i.e., facial expressions) and cognitive responses (i.e., coping strategies) [72.58]. This kind of model lends itself to more symbolic AI (artificial intelligence) implementations, with if-then rules [72.59, 60]. In contrast, dimensional theories posit that emotion and other affective phenomena are not discrete entities, but rather exist on a continuum of a continuous dimensional space [72.61]. Smith and Scott [72.62] proposed a three-dimensional (3-D) PAD model where P corresponds to pleasure (valence), A corresponds to arousal (intensity), and D corresponds to dominance (coping potential) [72.62]. Reference [72.63] mapped these appraisal dimensions to intensity varying expressions that can be computed as a weighted blend of basis postures corresponding to the main axes [72.63]. The core affect (the emotional state of the individual at any given time) is represented as a point in the 3-D space that is pushed around by eliciting events. Dimensional models are often used for generating the behavior of animated characters, as the dimensional space lends itself nicely to animation blending.

72.3.2 Example: A Synthesis of Emotion Theories in Action

Kismet is the first autonomous robot explicitly designed to explore socio-emotive face-to-face interactions with people [72.3, 51]. Research with Kismet focused on exploring the origins of social interaction and communication in people, namely that which occurs between caregiver and infant, though extensive computational modeling guided by insights from models of emotion [72.64]. Kismet was designed to be dependent on people to help it satisfy its goals and motivations.

Internally, Kismet's models of emotion interacted intimately with its cognitive systems to make affective appraisals about its interactions with the surrounding environment and people. These appraisals characterized the robot's interaction with its environment (e.g., *Is an object too close to the robot so that it might do damage?*, *Is that person speaking to me in a praising tone of voice?* etc.). These appraisals were tagged

with somatic markers [72.65] that characterized how these appraisals mapped to the robot's internal measures of arousal (A), valence (V), and stance (S), an action tendency to approach or avoid). The affective appraisals directly influenced the robot's behavior selection and goal arbitration processes. The somatic markers influenced the robot's core affective state – a continuously adjusted point within a three dimensional $[A,V,S]$ space. The core affect mapped to the robot's emotive expressions conveyed through vocal quality, facial expressions, and body posture [72.66]. Rather than simply triggering a set of discrete emotive expressions, Kismet's facial and postural expressions were continuously computed following a componential approach, as a weighted blend of basis postures of the face and body along the $[A,V,S]$ axes. This subtle variability in expressive behavior was important for enabling the robot to mutually regulate affective states with a person [72.67, 68]. Finally, the core affect and affective appraisals contributed to elicit adaptive behavioral responses (e.g., orient, search, avoid, etc.) as part of the robot's emotive responses (loosely inspired by the idea of emotion circuits [72.69]). Through a process of behavioral homeostasis [72.70], these emotive responses served to influence how people interacted with the robot in order to restore the robot's internal drives, goals, and affective states [72.67, 68].  VIDEO 557 illustrates Kismet's ability to recognize, express and interact with people using emotive cues. Ultimately, the purpose of this *dance* was to keep the robot in a *zone of proximal development* conceptualized by Vygotsky to be optimal for learning to propel the robot down a developmental path [72.71].

72.3.3 Emotional Empathy

For humans, the dynamic coupling of like minds through the actions of similar bodies is critical for acquiring human-like intuitions about the internal states of others. Dautenhahn [72.2] is one of the earliest works to explore *empathic* mechanisms of understanding others in social robot–robot interaction.

It is likely that emotional empathy in humans is learned, beginning in infancy. Various experiments with human adults have shown a dual affect–body connection whereby posing one's face into a specific emotive facial expression actually *elicits* the feeling associated with that emotion [72.72, 73]. Hence, imitating the fa-

Fig.72.5a,b Kismet and a young woman mirroring affect. Facial expression and affective tone of voice are tightly correlated: (a) mirroring interest/arousal; (b) mirroring negative affect

cial expressions of others could cause an infant to feel what the other is feeling, thereby allowing the infant to learn the association of observed emotive expressions of others with the infant's own internal affective states. Other time-locked multimodal cues may facilitate learning this mapping, such as affective speech that accompanies emotive facial expressions during social encounters between caregivers and infants. Using a similar approach, Breazeal et al. [72.74] posit that a robot could learn the affective meaning of emotive expressions signaled through another person's facial expressions, body language, and synchronized multimodal cues such as vocal prosody [72.68, 75] (Fig. 72.5). These time-locked multimodal states occur because of the similarity in bodies and body-affect mappings, and they enable the robot to learn to associate its internal affective state with the corresponding observed expression. In later work, they implemented a model of social referencing by which the robot, Leonardo, that combines models of *empathic association* with models of shared attention (Sect. 72.4.1).

72.4 Socio-Cognitive Skills

Socially intelligent robots, however, must understand and interact with animate entities (i. e., people, animals, and other social robots) whose behavior is governed by having a mind and body. In other words, social robots need the ability to recognize, understand, and predict human behavior in terms of the underlying mental states such as beliefs, intents, desires, feelings, etc. Psychology calls this ability *Theory of Mind* (also known as mindreading, mental perception, social common-sense, folk psychology, social understanding, among others).

This section reviews research in implementing models of human socio-cognitive skills and abilities on robots. Social robots shall need a diverse repertoire of such skills to realize their full potential in daily human life – to communicate, cooperate, and learn from people in a human-centric and human compatible manner.

For instance, social robots will need to be aware of people's goals and intentions so that they can appropriately adjust their behavior to help us as our goals and needs change. They will need to be able to flexibly draw their attention to what we currently find of interest so that their behavior can be coordinated and information can be focused about the same thing. They need to realize that perceiving a given situation from different perspectives impacts what we know and believe to be true about it. This will enable them to bring important information to our attention that is not easily accessible to us when we need it. Social robots will need to be deeply aware of our emotions, feelings, and attitudes to be able to prioritize what is the most important thing to do for us according to what pleases us or to what we find to be most urgent, relevant, or significant.

Furthermore, the behavior of social robots will need to adhere to people's expectations. Namely, people will apply their theory of mind to understand the robot in terms of these mental states as well.

72.4.1 Shared Attention

Scassellati [72.76] was one of the earliest works to pose the question of how to endow robots with a theory of other minds. Inspired by the theoretical viewpoints proposed from the study of autism (believed to be a deficit of theory of mind), Scassellati implemented a hybrid model of those models proposed by Leslie [72.77] and Baron-Cohen [72.78] where shared attention is viewed to be a critical (and missing) precursor to the theory of mind competence. This hybrid model was implemented on the humanoid robot, Cog. The robot was able to exhibit an assortment of social-cognitive skills such as joint attention, distinguishing an entity in the

environment as either being animate or inanimate, and imitating only entities deemed to be animate [72.79].

Several researchers have explored models of joint reference, guided by insights provided by developmental psychology and autism research [72.76, 79–81]. Normal human infants first demonstrate the ability to share attention with others at 9 to 12 months of age, such as following the adult's gaze or pointing gestures to the object being referred [72.78, 82]. In these works, joint attention is a learned process. For instance, the robot learns the visual motor mapping from the human's attentional cue (often using head pose as a popular indicator of what the human is currently looking at) to the motor commands necessary to have the robot look at the same thing. This process is often bootstrapped by having the human look to where the robot initiates its gaze. In Fasel et al. [72.80], the robot learns a model of joint attention because it discovers that the human's gaze is a reliable indicator of where there is something interesting to look.

Thomaz et al. [72.83] explore attention-monitoring behavior of a robot in a social referencing interaction. In the developmental psychology literature, the ability for babies to actively monitor that others are looking at the same thing is a strong indicator of shared attention [72.84]. Social referencing is considered to be an early demonstration of shared attention because the baby looks back and forth between the novel object and the adult's emotive reaction toward that object to learn the association between the two. To implement shared attention, the robot's attentional state is modeled with two related but distinct foci: the current attentional focus (what is being looked at right now) and the referential focus (the current topic of shared focus, i. e., what communication, activities, etc. are *about*). Furthermore, the robot maintains a model for its own attentional state and a model for the attentional state of the human. The robot uses the heuristic of looking time upon a shared object to infer the referent of the interaction. Once the referent has been identified, the robot monitors the attention of the human in order to associate their emotional reaction about that object to the intended target. Video  VIDEO 556 illustrates Leonardo's ability to interact and learn from a person via social referencing.

72.4.2 Mental Perspective Taking

This section explores this empathetic, self-as-simulator approach further to address more general challenges in endowing robots with mental perspective-taking abilities. These approaches are inspired and informed by

theories championed by neuroscience and embodied cognition called *Simulation Theory*.

Simulation Theory

Simulation theory holds that certain parts of the brain have dual use; they are used to not only generate our own behavior and mental states, but also simulate the introceptive states of the other person [72.85]. In other words, we engage in a process of perspective taking and mental simulation.

For instance, *Gallese and Goldman* [72.86] proposed that a class of neurons discovered in monkeys (called *mirror neurons*) is a possible neurological mechanism underlying both imitative abilities and Simulation Theory-type prediction of the behavior of others and their mental states. Further, *Meltzoff and Decety* [72.87] posit that imitation is the critical link in the story that connects the function of mirror neurons to the development of adult mind-reading skills. From the field of embodied cognition, *Barsalou et al.* [72.88] presents additional evidence from various social embodiment phenomena that when observing an action, people activate some part of their own representation of that action as well as other cognitive states that relate to that action.

Mirror Systems for Recognizing Actions

Inspired by these theories and findings, *Johnson and Demiris* [72.89] employ a simulation of visual perception to recreate the visual egocentric sensory space and corresponding egocentric behavioral space of the observed agent to increase the accuracy of action recognition. This approach is based on their **HAMMER** architecture (hierarchical attentive multiple models for execution and recognition) that takes a mirror neuron inspired approach to action recognition and imitation by directly involving the observer's motor system in the action recognition process. Specifically, during observation of another's actions, all of the observer's inverse models (akin to motor programs) are executed in parallel via simulation using forward models, and then compared to the observed action. The one that matches best is selected as being the recognized action. Perceptual perspective taking is needed to provide meaningful data for comparison. The simulated actions used by the observer during recognition must be generated as though from the point of view of the other person. They demonstrate this approach in an experiment where a robot attributes perceptions and recognizes the actions of a second robot [72.89].

Mental Perspective-Taking for Inferring Beliefs and Goals

Gray et al. [72.90] have implemented computational models of simulation-theoretic mechanisms throughout

several systems within Leonardo's cognitive architecture to enable the robot to infer beliefs and goal states of a human collaborator.

The robot reuses its belief-construction systems from the visual perspective of the human to predict the beliefs the human is likely to hold to be true given what he or she can visually observe. This enables the robot to recognize and reason about the beliefs held by a person, even when they diverge from the robot's own beliefs of the same situation.

In psychology, the ability to appreciate the divergent beliefs of another is classically demonstrated by the famous false belief task. In this task, subjects are told a story with pictorial aides that typically proceeds as follows: two children, Sally and Anne, are playing together in a room. Sally places a toy in one of two containers. Sally then leaves the room, and while she is gone, tricky Anne moves the toy into the other container. Sally returns. At this point the human subject is asked *Where will Sally look for the toy?*

The robot, Leonardo, has demonstrated its ability to pass these sorts of false belief tasks where it observes two humans playing the roles of Sally and Anne [72.91]. Within the robot's goal-directed behavior system (where schemas relate preconditions and actions with desired outcomes) motor information is used along with perceptual and other contextual clues (such as hierarchically structured task knowledge) to infer the human's goals and how he or she might be trying to achieve them (i. e., plan recognition).

72.4.3 Perspective Taking in Collaboration and Teamwork

By using a simulation-theoretic methodology, mental inferences made across different cognitive systems can interact in interesting and useful ways to support collaborative behavior where a robot offers its human teammate appropriate assistance.

Using Visual Perspective Taking to Resolve Ambiguous Referents

Trafton et al. [72.92] have developed and implemented visual and spatial perspective taking abilities based on mental simulation to support human-robot interaction and collaboration. Their cognitive architecture, *Polyscheme*, is designed to model how humans integrate multiple representational methods, reasoning, and planning methods to keep track of the world, including rich facilities for representing counterfactual worlds. It thus supports simulations of other people's visual perspective to reason about interactions and the world from this alternate point of view.

They have demonstrated these skills in a number of experiments, such as demonstrating the robot's ability to learn how to play *hide and seek* with a person where the robot learns what makes a good hiding place with respect to being completely occluded from the human seeker's point of view [72.93]. They have also demonstrated the usefulness of this system for a robot that solves a series of perspective-taking problems using the same frames of references and spatial reasoning abilities that astronauts do to facilitate collaborative problem solving – such as repairing a vehicle with another person that has a different vantage point [72.94]. For instance, the robot can handle egocentric requests (i.e., *hand me the cone to my right*), addressee-centric requests (i.e., *hand me the cone to your right*), or object-centered requests (i.e., *hand me the cone in front of the box*).

In Trafton et al. [72.92], a human interacts with the robot using a multimodal interface that supports speech and gesture. The robot's perspective taking skills are used to resolve ambiguous referents that can arise when a person asks a robot perform an action in relation to an object (i.e., asking the robot to *hand me the wrench* when there are multiple wrenches to choose from). In particular, a visual occlusion in the workspace might hide another candidate wrench from the person's viewpoint but not from the robot's viewpoint (Fig. 72.6). The robot can infer which is the intended object by taking the visual perspective of the human and applying principles of *joint salience* and *least effort*. If there still remains an ambiguity, the robot can act to resolve it by asking *which one?*

Providing Informational or Instrumental Support

Gray et al. have demonstrated the ability for the Leonardo robot to successfully infer its human partner's beliefs, desires, and intentions from real-time behavior during collaborative tasks. The shared workspace can have either visual occlusions [72.90] or can change dynamically where not all participants know of these changes [72.91]. The robot can integrate these mental state inferences to decide how to best help the person such as offering instrumental support (acting on the environment to help the human complete their goal) or provide informational support (giving relevant information the person needs to successfully achieve his or her goal).

Consider the following scenario: a helpful robot is introduced to two people, Sally and Anne. All three watch as Anne hides chips in a box to the left of the robot and cookies in a box to the right. Sally leaves the room, at which point Anne plays a trick on Sally by swapping the contents of the boxes and then locks both

boxes with a combination lock. Anne leaves, and Sally soon returns craving the chips she saw placed in one of the boxes. Sally remembers seeing the chips placed in the left box and attempts to open it by working the combination lock. The robot has matching chips and cookies that it can give out. What should the robot do to assist Sally?

Mindreading skills play an important role in this plan recognition scenario where the robot must observe Sally in real time to infer Sally's misconception of where the chips are (Anne switched the location when Sally was out of the room), to infer what her desire is based on her behavior (Sally never explicitly said she wants the chips), and to recognize that Sally's plan for how to get the chips is actually invalid (she is trying to open the wrong box). The robot has true knowledge of the situation, and must then reason about how to best help Sally get the object of her desire.

Gray et al. [72.91] (VIDEO 563) combines these three kinds of mental inferences to demonstrate intention recognition with divergent beliefs for collaborative robots. Specifically, for the case of informa-

Fig. 72.6 Robonaut using visual perspective taking to disambiguate the intended referent when asked to *hand me the wrench*. The human can only see one wrench, but the robot can see both. The robot correctly hands the wrench that both can see

tional support, Leonardo relates its own beliefs about the state of the shared workspace to those of the human based on the visual perspective of each. If a visual occlusion exists or an event occurs that prevents the human from knowing important information about the workspace, the robot knows to direct the human's attention to bring that information into com-

mon ground. For instance, Leonardo points to the box that actually holds the chips. For the case of instrumental support, Leonardo helps the person by directly giving the person a matching bag of chips. Gray and Breazeal [72.95] explore the robot reasoning and taking explicit action to deceive a human competitor.

72.5 Human Social Responses to Social Robots

72.5.1 Social Judgments

Anthropomorphic design is important for social robots given that the appearance, interface, and function of a technology or product impact how people perceive it, interact with it, and engage with it over time [72.12]. Robots and other technologies with humanlike design cues elicit social responses from people [72.96–99]. For instance, people have been found to respond more positively to artifacts that exhibit humanlike cues such as emotive expressions over those with a purely functional design, although user preferences were task and context dependent [72.100, 101]. Adding humanlike cues to a technological artifact can foster people's social connection to it, aid people in learning how to use it, and enhance liking, engagement, and the desire to collaborate [72.102–104]. Others have found that people tend to hold richer mental models of as anthropomorphic robots than mechanistic ones [72.103, 105]. Others have explored a number of anthropomorphic design features such personality, backstory, use of humor, and even the notions of self (e.g., referring to itself as *I*), deception, politeness, and moral regard [72.106–108]. However, it is important that the appearance and interface of the robot's design match its capabilities and the users' expectations or negative effects can result [72.109].

72.5.2 Physical Versus Virtual Embodiment

When considering the role and advantages of social embodiment, one might ask whether there is a difference between physical and virtual counterparts. Indeed, physical social embodiment offers a number of advantages over purely graphical representations. First, while many social interactions involve exchanging only visual and auditory cues, robots support communication and collaboration through physical contact as well. Robots support the joint manipulation of artifacts and the sharing of physical space with people. Both are important for all sorts of collaborative activities such as assembly and manufacturing [72.110, 111] search and

rescue [72.16, 53], domestic assistance [72.103], and more. Further touch is not only an interesting and important communication modality with noted health and therapeutic benefits, but it can also influence the social judgments people make of robots such as how caring or persuasive it is perceived to be [72.103, 104]. The modality of touch will be discussed further in section social touch [72.31, 39].

In addition, a growing number of studies that directly compare virtual to physical agents report that people show more trust, compliance, and enjoyment with physical robots [72.112–115]. Beyond user preference of physical over virtual agents, a number of studies have also shown improved human performance and outcomes on a wide variety of tasks ranging from games [72.112] to educational contexts [72.115], assistive tasks [72.114], health-related activities [72.116], and Wizard-of-Oz user studies [72.113].

Finally, because virtual agents are a representational form, interpretation and mapping may prove too challenging for individuals with cognitive or social deficits. Hence, robots may prove advantageous as therapeutic interventions for children with autism who can show little or no interest in forms on video monitors or televisions [72.117]. Finally, social robots tend to support face-to-face group dynamics [72.118] – while screens tend to *capture eyeballs* at the risk of diminishing face-to-face interaction [72.119]. This has important considerations for the design of learning technologies for young children, in particular, where supporting the participation of the parent in a social way is of great benefit to how children learn.

72.5.3 Social Stimulus to Learn About People

The impact of physically embodied social robots on human social responses has opened new applications for robots as an interesting tool to help scientists learn about human social behavior and judgments. People make a variety of social judgments through the dynamic exchange of nonverbal cues such as postural

shifts, subtle head gestures, arm gestures, facial cues, tone of voice, etc. Indeed, ample evidence indicates that humans regularly use specific cues, often without conscious awareness, to infer the motivations of others with some level of accuracy [72.120, 121]. If people employ such cues without conscious awareness, then it becomes difficult to use people as experimental confederates where such cues must be carefully controlled. Thus, in one paradigm, social robots can be used as a highly controllable social stimulus in the place of a confederate in human participant studies. This is particularly useful when trying to understand how human nonverbal cues influence people's social judgments, such as how trustworthy another is perceived to be from a brief encounter [72.122].

72.5.4 Social Rapport

One important skill for social robots is the ability to build and maintain social rapport with its user. Social rapport exists in the interaction between individuals. It creates a powerful interpersonal influence and responsiveness based on mutual attentiveness, positivity, and mutual responsiveness [72.123–126]. In joint activities, the ability to establish a good rapport often results in improved outcomes. For instance, students learn better when they have a good rapport with their teachers [72.127], patients are more adherent and have better health outcomes when they have a good rapport with their doctors [72.124], teams make better decisions and work more effectively when they share a good rapport with each other [72.128]. The quality of rapport between people is influenced by the exchange of nonverbal behaviors between individuals [72.129, 130]. Although the specifics of how people build a strong rapport with one another are still a topic of scientific inquiry, the more in-sync and open the participants' nonverbal cues are in relation to one another, the more positive rapport results. For instance, appropriate mirroring or synchrony of body posture, head movements, facial expression, and vocal prosody can all contribute to positive rapport. Open cues signal a receptiveness to interact, e.g., making appropriate eye contact, leaning toward another, and arm gestures that tend to not occlude the body or face.

Hence, when considering how social robots can effectively collaborate with people, their ability to build and maintain good social rapport with people (at least perceived rapport) is important. Thus, it is not just a robot's ability to perform such nonverbal cues that ultimately matters, but the robot's ability to coordinate them with those of people in real-time. For instance, researchers have explored the coordination of an agent's

nonverbal cues with people to improve rapport [72.56], engagement [72.32], trustworthiness [72.122], and deictic cues [72.131].

72.5.5 Social Support

Improved rapport also facilitates the ability of social robots to provide people with effective forms of social support. Social support is recognized to play an effective role in helping people to attain personal goals and improved outcomes in broad domains such as education, mental health, physical health, aging, coping, and more. It is conceptualized as the perception and actuality that one is cared for, has assistance available from others, and that one is part of a supportive social network [72.123]. These supportive sources can be emotional, instrumental, informational, or companionship. Emotional support, for instance, conveys to an individual know that they he or she is valued; it includes offering empathy, concern, nurturance, encouragement, and acceptance to name a few [72.124, 125]. Instrumental support concerns the concrete, utilitarian ways to provide assistance such as financial assistance, material goods, or services. Informational support includes offering useful advice, guidance, or information to help others problem-solve. Finally, companionship support gives someone a sense of social belonging and having another to participate in shared social activities. These forms of social support can come from people, professionals, pets, and even social robots.

The ability to provide a user with social support is one of the effective ways that social robots can help people through social means. Robots can provide this assistance through direct interaction with its user, or by helping to mediate the provision of social support from people (e.g., connecting people). A wide variety of social robots today are being developed to interact with people as tutors [72.132], learning companions [72.118, 133], coaches [72.116], domestic helpers for the elderly [72.134], therapeutic aids [72.21, 31], and more. Through dialog, nonverbal cues, expressive displays, and physical actions, these robots assist people by providing information, monitoring performance, offering feedback, incentivizing and sustaining motivation, giving encouragement, offering companionship, performing physical tasks, etc.

As such, social robots have broad applicability in many domains where it is a technology that can extend and augment the social support provided by people. This is particularly relevant for societal challenges, e.g., eldercare, health and chronic disease management, and education, where social support is recognized as being critical for positive outcomes, but where there is a rec-

ognized shortage of trained professionals to meet the demand. Further, whereas frequent meetings with human professionals is cost prohibitive, social robots have the potential to be used to *fill the gaps* in a cost-effective

way. Importantly, social robots are not being designed to replace or obviate human professionals, but rather to serve an effective tool that supports human networks in a scalable and cost-effective way.

72.6 Social Robots and Communication Skills

Communication implies an exchange of information through natural language. Thus, one might consider that very good **ASR** (automatic spoken-language recognition) is the primary function required to fulfill the communication skills for robots. However, *social* robots are expected to engage in casual communication with people in as natural a way as people communicate themselves. In such casual communication, information is often exchanged nonverbally as well as verbally. Thus, robots need to be well equipped to recognize people's nonverbal cues and to express nonverbal cues via their nonverbal behavior. The required computation even takes into account good perceptual and cognitive capability of surrounding environments in addition to the targeted person. This section introduces the history of research in social robots and communication skills, and provides insights for future challenges.

72.6.1 Verbal/Nonverbal Communication

Historically, even first-generation humanoid robots developed in the 1970s had primitive capabilities for communicating using natural language. For instance, WABOT and WABOT-2 had a conversation capability in natural language, which is based on the model as simple combinations of speech input/output mappings [72.135, 136].

Furthermore, early pioneers had noticed the importance of nonverbal information in human conversation. Nonverbal behavior was classified into three roles:

1. **Regulators:** expressions such as gaze, poses, and vocalizations that are used to regulate/control conversational turn-taking.
2. **State displays:** indication of internal state including affect, cognitive, or conversational states that improve interface transparency.
3. **Illustrators:** gestures that supplement information for the utterance. These include deictic gestures (pointing) and iconic gestures.

In this scope, nonverbal information is considered as supplemental. It is natural language that communicates the primary information in turn-based exchanges. We provide examples below.

Regulatory Cues

Even some of the earliest social robots displayed nonverbal information to regulate interactions with people. Hadaly 2 was the first robot to use mutual gaze as a nonverbal cue to regulate conversation [72.137, 138]. The mutual gaze is approximated using face recognition to determine when the human's face was facing the robot; when a mutual gaze occurred, Hadaly 2 expressed readiness to commence conversation by blinking its eyes. People's gaze toward a robot is also considered cues to inform whether he/she is engaging in the conversation with the robot [72.139].

Other examples are Kismet [72.3, 140, 141] and Leonardo [72.33, 142], which had the capability for nonverbal cues called envelope displays to regulate the exchange of speaking turns. Backchannelling cues were found to reduce stress and cognitive load during complex human-robot teaming task (Fig. 72.7). See  **VIDEO 559** for how Kismet uses envelope displays to regulate speaking turns with people. The regulatory role for a speaking turn is demonstrated in multi-party interaction too. People tend to make eye contact and raise their eyebrows when they are ready to relinquish their speaking turn and tend to break their gaze and blink when starting their speaking turn. Recognition of these cues was implemented for smoothing and syn-

Fig. 72.7 Backchannelling cues were found to reduce stress and cognitive load during complex human-robot teaming task. Teams where the robots engaged in backchannel cues to human requests also tended to find more items in a search and retrieve task (after [72.16]),

 **VIDEO 555**

chronizing the exchange of speaking turns. Gaze is also known to convey the speaker's intention who may take the next turn. *Mutlu* et al. have successfully replicated it in human–robot interaction [72.143, 144]. *Kirchner* and *Alempijevic* revealed that gaze is also effective in communicating who should receive an item provided by a robot [72.145]. In opposite way, gaze was also used as a cue to interpret whether one would wish to take turn [72.146].

Paralinguistic information is also processed. People frequently provide short acknowledgment utterances (e.g., *uh-huh*, *um-hmm*, *huh*, etc.) as the robot explains something. These responses are either acknowledgments, or ask-backs. It is very difficult to distinguish these two kinds of utterances from only the linguistic information as represented by the transcription of the utterance. *Fujie* et al. demonstrated a method to distinguish the utterance as either an acknowledgment or an ask-back from the prosody of utterance [72.47].

State-Display Cues

The facial expression and gaze were used to indicate the conversational or cognitive state of a robot. Such state-display cues make the robot's internal state more transparent to a user and thus enables him/her to better understand the robot's state. For instance, ROBITA used the tightness of its facial expression to indicate readiness to engage in conversation; a tight face was used to express conversational readiness, while a loose face communicated a lack of readiness to engage [72.147]. Emotional state and attention target can also be displayed nonverbally (Sects. 72.3 and 72.4).

State of listening and level of understanding are also displayed nonverbally. Human listeners use back-channel responses, such as head nods to convey the fact that he/she is successfully following the conversation. Imitating human behavior, robots indicate their state of listening using head nods [72.148], facial expressions [72.5], and bodily motion ([72.149] and VIDEO 810). Such state-display cues are used in a human-like telepresence robots to indicate operators' state of being engaging to the conversation [72.150, 151].

Another back-channel signal is an expression of confusion by the listener (verbal or nonverbal). This flags the speaker to stop and try to repair the broken communication. Robots such as Leonardo and ROBITA use facial displays of confusion when speech recognition fails in order to intuitively communicate to the human that he or she should repeat their last utterance.

There were robots that process humans' back channel feedback [72.32]. A sophisticated head nod recognition system was developed whereby the robot, Mel,

could successfully distinguish small feedback nods from other kinds of head nods such as those that communicate agreement. Mel used this information to determine its own nodding behavior in order to be an appropriate response for the human. In a series of human subject studies, *Sidner* et al. found these nonverbal cues to enhance the social engagement of the robot to people [72.32].

Illustrator Cues

Deictic gestures have often been implemented in robots for pointing to an object, such as using index-finger pointing [72.152, 153], gaze [72.143], and the combination of the two [72.74, 154–157]. Other types of gestures, such as iconic gestures [72.156] and region pointing ([72.158] and VIDEO 811), were also successfully used in robots. The effect of gestures has been successfully demonstrated. For instance, in a direction giving scenario, even though turn-by-turn direction is verbally given thus could be comprehend without gesture, supplemental pointing gesture improved listeners' comprehension about the given direction [72.159].

A number of robots are able to recognize deictic gestures of a person conveyed either through pointing gestures or head poses. For example, Leonardo is able to infer the object referent in an interaction by considering a number of factors including pointing gesture, head pose, and speech. *Sugiyama* et al. associated verbal spatial deixis and pointing gestures to better recognize the pointed target ([72.160] and VIDEO 807). *Brooks* and *Breazeal* [72.153] developed a deictic recognition system that enabled a robot to infer the correct object referent from correlated speech and deictic gesture. Interestingly, it was found that the accuracy of the human's pointing gesture is surprisingly poor. As a result, the deictic recognition system relies on coordinated speech and gesture information, with spatial knowledge provided by a three-dimensional (3-D) spatial database constructed by the robot using real-time vision, and a deictic spatial reasoning system. This system was successfully demonstrated on the dexterous humanoid Robonaut developed at National Aeronautics and Space Administration (NASA) Johnson Space Center (JSC) (Fig. 72.8b) where the human points to and labels a set of four bolts on a wheel to be fastened in order by the robot.

72.6.2 Mechanisms for Human–Robot Communication

Mechanisms of turn-based communication are well studied. In linguistics, it is considered that conversation is formed as the repetition of turn-taking [72.161].

Fig.72.8a–c Examples of conversational robots: (a) ROBITA performing group conversation; (b) Robonaut interpreting the pointing gestures of a human to determine which nut to fasten on the wheel; (c) Leonardo uses gaze and joint attention to ground the human's pointing gesture for the desired referent

There is one speaker who takes floor and speaks while listeners listen to him/her [72.162]. When the speaker finishes speaking, then the floor is taken by one of the listeners. There could be bystanders who also listen to, but do not intend to take turn. This turn-based model is the typical model used in dialog modeling [72.163]. That is, a dialog management system identifies who owns floor, recognizes words in utterances the speaker spoke, and generate utterance when the system takes floor, often implemented with series of rules. It is successfully extended for human–robot communication. For instance, *Nakano* et al. developed rule-based architecture in which the planner deals with robot's task-based actions as well as dialog management [72.164]. *Scheutz* et al. developed software architecture, named DIARC. It uses a rule-based planner that receives inputs from all perception modules, and addresses effect and goal-directed actions in addition to natural language dialog management [72.165]. In such an approach, the robot communicates through utterances accompanied with nonverbal cues [72.166]. Some systems deal with multi-party dialog, in which robot's gaze-cue (Fig. 72.8a) is used to regulate who is the addressee, the active listener

who is expected to take the next turn [72.143, 167–171].

Researchers have also been well aware of the importance of the time-sensitive nature of communication. For instance, interruption in the middle of a speaker's turn has also recently been taken into account in dialog management systems [72.164, 172]. *Chao* and *Thomaz*, proposed more elaborated model, in which time-synchrony in verbal and nonverbal cues, e.g., gaze and gesture, are addressed using a Petri-net-based representation [72.173]. Empirical studies have revealed what is good synchrony and timing. For instance, *Yamamoto* and *Watanabe*, have studied synchrony within a robot's utterance and motion, and revealed that people prefer the robot whose utterance is slightly delayed from the start of its motion [72.174]. This would mirror what humans do everyday, as it is reported that humans' gestures are performed slightly ahead than their utterances [72.175]. *Shiwa* et al. revealed that people prefer small delay in the robot's response, and conversational filler such as *etto* would be useful to buy time when the robot's response is delayed ([72.176] and VIDEO 806).

However, while above studies are under the assumption that information is communicated through turn-based dialog, recent studies have revealed more dynamic cases of human–robot communication, in which the way robots communicate information is sometimes out from the turn-based dialog paradigm. For instance, during the moment a robot and a person are going to initiate interaction both of them communicate their intention that they would like to meet and talk. A couple of studies investigated a way for a robot to express its intention to welcome the initiation of interaction [72.177]. When the target user is seated, *Dautenhahn* et al. revealed that they prefer the robot approach from side ([72.178] and VIDEO 258). Figure 72.9 shows a scene in which the robot approached to pedestrians. *Satake* et al. revealed that such interaction failed if the robot failed to communicate its intention to talk. As the robot was operated in noisy shopping mall, when it used only verbal utterance, the robot was simply ignored. Instead, they found that the robot needs to communicate its intention nonverbally. It needs to approach from a frontal direction and needs to be responsive in adjusting its body orientation toward the targeted person; such nonverbal behavior made the robot more success in initiating conversation with pedestrians [72.179].

Pedestrians also communicate their intention nonverbally; for instance, when he/she does not wish to talk to the robot, they avoid approaching to the robot. Thus, a robot could use the proximity information to estimate people's willingness in initiating interac-

Fig. 72.9 A robot that approaches pedestrians

tion. Michalowski et al. classified spatial zones around a robot, and let the robot talk to the person if he/she approached to the robot and entered to social distance [72.177]. There are some empirical studies about proxemics that revealed that people often prefer to stay at social distance when they talk to a robot [72.180–182].

Joint attention (as introduced in earlier Sect. 72.4) can be silent. Figure 72.10 and VIDEO 257 show a scene where a person share his attention target nonverbally with the robot. The person is curious about the computer and stands in front of it; then, the robot moves to the location convenient to explain the object. When the person moves to the other exhibit, the robot follows him and explains the one in front of him. Here, it is their standing position that communicates the target of attention [72.183, 184].

These examples show the cases where communication is not necessarily turn-based. This is because information can be exchanged nonverbally in such casual communication. Unlike the speech channel that needs to be typically occupied by only one speaker (speaking person), nonverbal signals can be mutually exchanged at the same time. For instance, when a pedestrian and a robot meet, their positions continuously change while they walk which communicates whether they would like to initiate conversation. As so-

cial robots aim to operate in people's daily environment, such a casual and nonverbal exchange of information is not a trivial part of human–robot communication. The research for fully unveiling required mechanism for such continuous exchange of social signals is still premature.

On the other hand, some studies started to highlight the needs of a mechanism that connects communication and background knowledge. It is revealed that the model of common ground makes daily communication effective [72.185]. For example, a direction-giving scenario would be a case where environmental knowledge is useful. For instance, when a robot provides directions (Fig. 72.11 and VIDEO 259), it could be more comprehensive if the robot is aware of a visible landmark so that it could say *please turn at the book store* instead of saying *please turn at the third corner* [72.186]. Thus, a good model of environment, e.g., [72.187], would greatly improve a robot's capability in communicating about a route. Moreover, if a robot has a model of users' memory of location, it could provide destination-based direction, such as *a café is nearby the book store you just visited* [72.188], which is much easier to comprehend than complex turn-by-turn destination like *to go to a café, please turn right at first corner, turn left at third corner, and ...*

Fig. 72.10 A person and robot implicitly share the target of attention via spatial formation

Fig. 72.11 A robot that provides directions (after [72.189])

72.6.3 Challenges

To summarize, turn-based conversation has been studied to a certain degree. However, social robots often engage in casual communication in which robots would need to deal with social signals and background knowledge. Here, we denote a couple of key challenges.

Revealing Repertory of Communication Skills

Previous studies started to reveal different forms of communication where various perceptual and cognitive capabilities are required. Early studies have revealed the importance of social signal processing, like recognizing and expressing gaze and facial expressions. Studies about initiation of conversation have revealed the mutual real-time exchange of information via their positions. Studies about giving direction

demonstrated further needs of associating language and environmental knowledge, e.g., a *cognitive map*, how people perceive environments, and remembering landmarks.

To what extent do we need to cover repertoires? We believe that there could be many elements we will find. Many of them might be interrelated with perception and cognition. Such a case would improve our understanding about what communication skills truly are. Thus, one of the important challenges is here.

Architecture for Communication Skills

Along with finding out the repertory of communication skills, the other important challenge is to deal with the integration, i. e., the architecture of communication skill. Moving from a turn-based structure to a dynamic structure is the real challenge.

72.7 Long-Term Interaction with Robot Companions

A number of social robots have been introduced as companion robots. Companion robots may have the sole purpose of providing companionship, e.g., in studies using toy robots such as the Pleo [72.190], but often they combine two aspects: *being useful*, i. e., being able to carry out certain tasks for the user, and carrying those tasks out in a manner that is socially acceptable [72.191]. The latter notion has been used, e.g., in several European projects [72.192–195]. The notion of a companion often entails repeated and long-term interactions. This poses particular challenges not only for the design of the robot, the interaction design, the choices of tasks/settings/scenarios, but also on the how to ensure satisfactory and successful interaction with the robot.

72.7.1 Robot Companions

Recently more and more researchers are moving toward studying application areas that develop such companion robots, e.g., the use of robots in assistive and rehabilitation robotics. The use of robots to assist elderly users in their homes, with a view to extend the period they can stay and live independently in their own homes, is currently being studied extensively by different research groups worldwide. Several companies are also marketing their robots as such assistive companions, e.g., the Wakamaru robot (Mitsubishi Heavy Industries Ltd) that was introduced in 2005, or the Human Support Robot (Toyota) revealed in 2012. In addition, numerous research prototypes exist, e.g., Cody (Georgia Tech), Herb (CMU), Care-O-bot 3 (Fraunhofer), Hector (CompanionAble project).

A number of tele-presence robots have been developed, but this chapter will focus on autonomous or partially tele-operated companion robots. Note, Cody targets the domain of patient hygiene care that is related to issues discussed in the section on tactile human–robot interaction. Regardless of whether human–robot interaction with companions include tactile interaction, or is a hands-off approach (Chapt. 73), developing such system involves a careful study of the roles and functions of such robots in the application domain, and of users’ perception of and attitudes toward such a system.

Figure 72.12 and  VIDEO 218 show the Care-o-bot robot (Fraunhofer) used in the ACCOMPANY project on home assistance for elderly people. The robot is shown in the University of Hertfordshire’s Robot House, a domestic setting for experiments into robot home assistance where participants regularly visit for human–robot interaction sessions. Such *living lab* settings are increasingly being used to design, experiment and evaluate innovative systems (e.g., the European Network of Living Labs, [72.196]). Providing such environments facilitates progress toward complex robotic systems that can be deployed in real-life environments.

72.7.2 Engagement and Long-Term Relationships

The concept of a robot companion entails repeated, long-term interactions, which may also afford the development of *relationships* between robots and people. Relationships with robots can take many shapes and forms, and the formation of relationships will be influenced by many factors. For example, the specific

role of the robot (Butler? Friend? Tutor? Assistant? Tool? etc., [72.197]) will matter, as well as the robots' specific embodiment and behavioral and expressive repertoire that is often used to present them as *relational artifacts* [72.198, 199] that are designed to build and maintain social-emotional relationships with users.

Many applications with social robots do only involve short-term interactions, e.g., robots meant to function as a museum guide [72.200] and  VIDEO 808, a receptionist, etc. Here, the *novelty effect* can often be exploited, i.e., the general interest that many people have in new robots. However, after repeated interactions this effect can wear off and people can lose interest in a robot. Thus, a main research challenge is how to keep people engaged in the interaction and keep them motivated to interact with the robot. Establishing a useful and enjoyable relationship with a robot is not an easy task. And what exactly is *long-term*? Tanaka et al. [72.22] mentions at *10-hour barrier* (total interaction time), Sung et al. [72.201] pose the goal of long-term interaction over more than 3 months as a main challenge. Hüttenrauch and Severinson-Eklundh [72.202] performed a user study with the service robot CERO meant to assist one user over three months in an office environment. Kanda et al. [72.189] and  VIDEO 809 investigated a partially tele-operated robot over a 25-day period. The nature of these interactions depends on whether studies take place in a school, a home, a public place, etc. It will also depend on the frequency and duration of the interaction, e.g., how many interaction episodes per time interval does an individual have with the robot?

There is also the issue of quantity and quality of interaction that may be realized very differently in different application areas of social robots. More and more studies are bringing robots into the *wild* [72.203].  VIDEO 564 shows how preschool age children interacting with a storytelling learning companion robot during repeated encounters over a 2 month period. Personalization of the robot stories to the children led to improved vocabulary learning. Field studies are often said to be preferable, and more ecologically valid than data collected in the laboratory. However, practical, technical, and methodological constraints may limit the length and nature of the field studies. Also, bringing a robot in the *wild* does not necessarily make the interactions with people more natural, and the more *messy* conditions pose hard methodological problems and can often interfere with controlled data collection and statistical data analysis [72.204]. A field study by Heylen et al. [72.204] placed a simple dialogue Nabaztag (rabbit) robot in a few people's homes over 10 days, and it illuminates a number of those real-life problems with

field studies which impacts on the validity of the results that can be gained and on the user experience. The latter will then ultimately decide on whether people will consider a long-term companion robot *amusing or a nuisance* [72.204]. A taxonomy to characterize studies in the *wild* for child-robot interactions is provided in Salter et al. [72.205]. Systematic analyses of different experimental conditions and tasks, settings, etc., whether in the laboratory or in field studies, will help the planning, design and comparison of different long-term studies.

Note, often the expectations of users are not met by the robot's design and abilities, and nor does it fit into daily activities of users [72.190]. The advancement of robot technology and knowledge of HRI will enable more and more field studies, in schools [72.206], nurseries [72.22], private homes [72.190], care homes [72.31], etc.

In many of the above long-term studies, commercially available robots have been used. The reasons for this are not only availability, but also robustness and reliability, as well as safety. The use research prototypes in field studies should always entail securing Institutional Review Board (IRB) approval to meet ethical guidelines when human participants are involved. Even prototypes that are generally safe to use, may still have *cables sticking out*, etc. Hence often it is a necessity to have researchers present at all times during these studies. Research prototypes are also by their very nature more prone to break down, and again this requires the constant attention of researchers. The design of research prototypes is also often not ideally suited for a field study, e.g., wheels when being used on cluttered surfaces, etc. Interesting insights on those *practical* but nevertheless very important points can be found, e.g., in Hüttenrauch et al. [72.207] where a modified Peoplebot (Mobile Robotics) robot was brought into eight different homes for approximately 1 hour each in order to study spatial management in HRI situations. Note, even when leaving a robot alone with a person or family in their own home, people may still be acutely aware of the *experimental* nature of the interaction [72.204].

Establishing and maintaining relationships between users and robots in long-term interactions needs careful consideration, and many insights can also be gained from related long-term studies with virtual agents, e.g., as exercise advisors [72.208, 209].

72.7.3 Robot Home Companions for Supporting Elderly Users

Several HRI studies in the home focus on the use of a companion robot for the general population. Koay et al. [72.210] report on a long-term, 5-week study

in a domestic environment with a partially remote-controlled robot involving several different scenarios (e.g., a collaborative task, sharing physical space, recording and revealing personal information, interrupting a person to serve them, and seeking assistance from a person using combinations of physical and verbal cues). The results highlight concerns and expectations that people have in such scenarios that are relevant for the domestic use of robots. Note, the robot used in this study was partially remotely controlled, which allowed the investigation of complex scenarios.

Due to demographic changes, a lot of interest exists worldwide into developing robot technology for the care of elderly people that would allow elderly people to remain in their own homes for longer, or to provide assistance in sheltered or otherwise specifically designed environments. A robot may assist an elderly person in the home in different ways, e.g., provide physical assistance (standing up, walking, fetching and carry objects, etc.), social assistance (e.g., engaging the user in interactions with other people) and cognitive assistance (e.g., reminder functions).

In HRI, there is prior work investigating robot's ability to remind users of future or prior activities. Autominder using the Nursebot represents an initial attempt to make reminders more intelligent and dynamic [72.211]. Intelligence and dynamics were also key aspects of the system proposed by the Robocare project [72.212]. More recently, the KSERA project [72.213] focused on the ability of the robot to draw on information not readily available to the user as well as its ability to persuade in order to safeguard the health of the user. Other examples for assistance and reminders for elderly people with dementia through multimodal interactions and smart-house integration include the EU FP7 CompanionAble project and the MOBISERV project [72.214]. The project, Florence [72.215], introduces a commercially available robot as an autonomous lifestyle device for ambient assisted living; it provided multiple services to users including an agenda reminder application that allowed the elderly to share information with caregivers, etc. The European projects SRS [72.216] and ACCOMPANY [72.217] both use the care-o-bot 3 (Fraunhofer) (Fig. 72.12) as their target robotic platform. While SRS involves the use of the robot in a remote-control scenario, the ACCOMPANY project develops fully autonomous behaviors for an empathic and assistive home companion.

Several projects combine a robotic companion with an intelligent smart/ambient environment as part a variety of ambient assisted living (AAL) solutions to assist with older adults, or people with disabilities, to live independently by providing support in activities of daily

Fig. 72.12 Care-O-bot 3 robot (courtesy of Fraunhofer)

living (ADLs). Such topics are currently being studied world-wide. See, e.g., the quality of life technology (QOLT) [72.218] Centre of Carnegie Mellon University or the Centre for Affective Solutions for Ambient Living Awareness (CASALA) [72.219].

72.7.4 Example: Long-Term Interactions with a Robotic Weight Loss Coach

A number of recent studies investigate the use of robotic companion as health *coaches* or *advisors*. Kidd and Breazeal developed Autom [72.116, 220] (VIDEO 558), a robot specifically designed for long-term interaction with people in the role of a robotic weight loss coach. Autom has a clear function and role, but also needs to interact with users in a socially acceptable and comfortable manner, so that users intuitively understand the robot, are willing to engage with the robot, and *listen* to it. This robot is also an example how academic research in long-term HRI can lead to new innovations and commercialization. The main purpose of the robot is to help the user to lose weight, trying to persuade the user to change his or her behavior [72.221].

A key ingredient supporting this functionality is the creation of a relationship between the user and the robot. Autom is thus an example of a robot that presents itself as a relational artifact and encourages people to develop social-emotional relationships with them [72.198, 199]. Autom uses a psychologically inspired relationship model, with the robot's role as a caregiver. It engages the use in a dialog modeled after patient-care professional dialog to provide social support (Sects. 72.5.4 and 72.5.5) in order to build a working alliance as well as to be helpful, persuasive, positive, and supportive. For a health care coaching robot, where behavior change is a central objective,

such a relationship is very important. People who need to lose weight typically do not lack the intelligence or knowledge necessary to understand that weight loss would improve their health and general well-being. The motivational factor is often a crucial point, so a weight loss robot's role on providing social support is different from that of a kiosk robot only needs to provide information.

A long-term study with 45 participants an Autom prototype robot over 6 weeks was the first study designed to create behavior change in people with a weight management goal (Fig. 72.13). The results were very encouraging: participants developed a close relationship with the robot, and they tracked their calorie consumption and exercise much longer when using the robot, compared to other methods (a computer running the same dialog or a paper log for manual entry). Since these factors are indicators of longer term weight loss success, the study provided evidence for the effectiveness of sociable robots for long-term HRI [72.116].

72.7.5 Challenges

Many of the projects studying the use of robot companions (e.g., supporting elderly users, providing assistance in therapy, or helping in office environments) are still at an initial stage. Future results from extensive, long-term, multi-site and even cross-cultural evaluation studies are still needed in order to illuminate the usability, usefulness, and acceptability of such systems. It is particularly advantageous if the same research platform is used in different projects so that direct comparisons and the sharing of research developments are possible.

The challenges of supporting engagement in long-term studies are beginning to emerge. New sensors and interfaces, such as brain–computer interfaces, could provide richer information on people's emotional, attentional engagement states when interacting with a robot. Robots are providing richer social cues to explore the whole spectrum of human–human interaction modalities, e.g., using gaze, gesture, proxemics, dialogue, contingency, etc. [72.177, 222–226]. Measuring engagement in real time and allowing a robot to respond to it is a key challenge. In a user study with 37 participants and a robot that could perceive user engagement Sidner et al. [72.32] found that engagement gestures were perceived more positively than a robot without such gestures. Rich et al. [72.139] proposed an initial computational model for a robot to model engagement, based on the recognition of different events involving gesture and speech.

A clear framework of what engagement means in HRI in general, and for long-term HRI interactions

Fig.72.13a,b Autom, a weight management and exercise coach. (a) The Autom prototype robot developed at MIT; (b) the commercial version of the Autom robot

in particular, is needed and will need to be validated in extensive testing. Several other proof of concept studies of robots that adapt to user engagement and interaction show encouraging results. François et al. [72.227] evaluated a robot that adapts to user interaction in a therapeutic context based on tactile information (how children touched the robot), while Szafir and Mutlu [72.228] demonstrated how a robot can adapt to the engagement of the user, utilizing techniques from brain–computer interfaces in order to assess engagement. Future applications of this research into adaptive robots target educational settings where a teacher robot can automatically adapt to the pupils' engagement, or therapeutic/rehabilitation applications where the robot can automatically adapt to the patient's needs and preferences in light of therapeutic objectives.

Future research needs to illuminate how best to design interaction and embodiment of social robots that are successful in long-term interactions with people. Since adding social interaction skills to a robot is costly, the identification of a set of robot characteristics (appearance, behavior, cognition) that are necessary and sufficient to create meaningful, acceptable, and efficient long-term interaction with a robot would be beneficial. Here, it is important to provide frameworks that connect to empirical methodologies, cf. the discussion of a conceptual and methodology framework for robot believability in Rose et al. [72.229]. Note, while predominantly humanoid or zoomorphic robots are currently being used in long-term HRI experiments, even mechanically looking robots such as the Roomba robot may invite people to develop a social-emotional relationship with its users [72.201, 230].

Using robots in long-term repeated interactions with people also involves a number of ethical issues, as it has already been highlighted also for embodied conversational agents and virtual characters [72.208]. While in some applications the robot may have a useful function if portrayed as a care-receiver [72.133], in most applications the companion robot should provide

care to its users [72.191]. As pointed out by *Turkle* et al. [72.198, 199], robots that present themselves as relational artifacts may influence people's understanding and expectations of the nature of social relationships and friendship. Ethical issues are particularly important when users are vulnerable people such as adults with special needs, elderly people, or children. Many researchers have commented on these issues [72.231, 232].

Practical issues can also become crucial to the acceptance of a robot for long-term interaction, as it has been highlighted in a long-term study with *Pleo* – a commercially available robot, but which requires maintenance that does not fit easily into people's routines [72.190]. *Fernaes* et al. also bring up the important issue of interaction design that needs to support

long-term interaction, an issue that was also brought up in user feedback from the participants in their long-term study. Novel approaches to how to design human–robot interaction may be required to facilitate long-term use of companion robots [72.190], and in real-world settings attention must be paid to how the robot technology is being introduced to people and how people and robots must adapt to each other [72.230].

Recently, the blending of virtual and robotic characters area a growing area of research whereby seamless transitions from a virtual to and from a robotic character [72.233], or migration between different robot and other digital embodiments [72.234] pose interesting challenges for future long-term companions. Indeed, it may change the nature of what we usually perceive as a *companion robot* [72.148, 233, 235–242].

72.8 Tactile Interaction with Social Robots

In robotics and artificial intelligence research, tactile interaction has long been exploited primarily as a necessity to enable, e.g., collision detection, grasping and object manipulation, particularly in combination with vision and other sensor modalities, and led to adding touch sensors to a robot's gripper or hand [72.243].

72.8.1 Touch for Social Interaction

However, the importance of *human–robot* tactile interaction has been highlighted recently in a number of research projects, inspired by evidence from human–human interaction and child development. The recent interest in the *sense of touch* goes beyond the necessity of touch for interactions with the physical environment, but focuses on the important role of tactile interaction in interactions with the social environment. For instance, *Siegel* et al. [72.244] found that social touch, such as shaking hands, can impact how persuasive a robot is perceived to be [72.244]. In other work, the same kind of touch can have a different impact on people's response to the robot depending on the context [72.245].

Indeed, humans are born as *tactile creatures*. Physical touch is one of the most basic forms of human communication. In human development, touch plays a crucial role in developing cognitive, social, and emotional skills, as well as establishing and maintaining attachment and social relationships. Deprivation of touch in early child development can have devastating effects on a child's development [72.246]. A comprehensive survey on communicative functions of touch in humans and other animals can be found in *Hertenstein* [72.247].

72.8.2 Touch Sensors and Mechanisms Used for HRI

Recently, more and more social robots are being equipped with tactile *skin*, thus allowing the robot to react according to the person touching the robot. Recent trends, e.g., in the European project *Roboskin* [72.248] tend toward covering the whole, or most of the robot's body, see e.g., *Schmitz* et al. [72.249] for an example using modular capacitive sensors to cover the humanoid robot *iCub*. Related work by *Dahiya* et al. [72.250] surveys a variety of different technological approaches toward tactile sensors and mechanisms of tactile sensor for robots. They show how one may take inspiration from biological tactile sensors in humans and derive design hints for robotic tactile sensing. *Stiehl* et al. [72.251] designed a tactile system inspired by the human skin as well as somatic processing [72.251], and was later developed to recognize social and affective communicative intent of how a human touches the robot [72.252, 253]. The new compliant skin technology developed in the *Roboskin* project has two primary functions: (a) to allow a robot to operate safely and efficiently, and (b) to use tactile sensors for communication, interaction, and cooperation with people.

The field of tactile human–robot interaction is indeed a growing area of research, and a recent survey discusses tactile *HRI* from the perspectives of the types of interactions that may occur between a robot and a human, and the types of sensors that allow to detect these interactions in various robotic systems such as the *Robovie* series of robots, *RI-MAN*, the *Hugable* robot [72.253], or *Paro* [72.254]. Note, equipping

a robot with tactile sensors may add its functionality, but in some cases the *sense of touch* is crucial for the key functionality of the robot (e.g., in the case of Paro [72.251] with a therapeutic/care function, or in the case of the Huggable to improve social relationships [72.255]). Many toy robots built primarily for human–robot interaction have touch sensors for petting and stroking, e.g., the AIBO or more recent Pleo robots. Indeed, the use of tactile HRI to support human–human communication over the distance is a promising area of research [72.255–258]. Tactile feedback can also improve teaching a robot by demonstration [72.259].

In order to realize robots' capability of a *sense of touch*, there are difficult sensor processing and perception problems to be addressed. One problem is that we need to identify the geometrical relationship between a number of sensors embedded in a whole body of a robot and body parts being touched when sensors are activated. For better perception of various touching, one can embed sensors into or under a soft skin. For instance, Robovie II-F has 274 sensor elements (Piezofilms) embedded in soft silicone rubber (Fig. 72.14). Tactile action activates multiple sensors at the same time, thus nearby sensors are all activated when touch action occurs to one place of body. For this problem, Noda et al. [72.260] took a bottom-up approach using observed signal patterns. Their method works in a self-organizing manner to identify mapping between signal patterns and touched location.

The second problem is the semantic relationship between signal pattern and people's communicative intention of touch action. For instance, Tajika et al. [72.261], applied clustering method for signal pattern to retrieve hierarchical structure of haptic actions. For instance, tickling-chest (Fig. 72.15) is found to be similar to stroking-chest, grouped together as lightly touching-chest action. Knight et al. [72.262] developed an algorithm based on identification of typical touch types, such as tickle, pet, and poke. Yohanan and MacLean [72.263] categorized humans' intent to communicate affect state and mapped touch action to each category, for example, comforting intent is mapped with actions like stroke and pat. Stiehl and Breazeal [72.264] trained a neural net to classify touch according to affect and communicative intent by recognizing types of socio-affective touch (e.g., pleasant or unpleasant ways of touching or teasing based on the way a person tickles, touches, pats, slaps, rubs, squeezes, etc.)

François et al. [72.227] describe an algorithm for pattern recognition in HRI, the cascaded information bottleneck method and apply it to real-time autonomous recognition of human–robot tactile interaction styles. This method uses an information theoretic approach

Fig. 72.14 An example of layouts of piezofilm sensors embedded in a soft skin (left)

Fig. 72.15 A child tickling the chest of a robot

and enables to progressively extract relevant information from time series. An evaluation with real interaction data obtained with a Sony AIBO robot shows that the algorithm is capable of classifying interaction styles (frequency and gentleness of the interaction), with a good accuracy and a very acceptable delay. The cascaded information bottleneck method was later successfully applied to create a socially adaptive robot that can recognize and adapt to children's play styles in real time [72.265]. The robot rewards well-balanced interaction styles and encourages children to engage in the interaction. The potential impact of such an adaptive robot in robot-assisted play for children with autism is evaluated through a study conducted with seven children with autism in a school. A statistical analysis of the results shows the positive impact of such an adaptive

robot on the children's play styles and on their engagement in the interaction with the robot.

72.8.3 Example: Teaching Children with Autism About Tactile Interaction

Using robots for the therapy and education for children with autism was first proposed by *Kerstin Dautenhahn* [72.266, 267] and it has recently attracted a lot of attention in the research community. A number of such approaches focus on *robot-assisted play*, since play has a crucial role in a child's development. During play, children can learn about themselves and their environments as well as develop cognitive, social, and perceptual skills. Autism, or better autistic spectrum disorders (ASD), is a life-long development disorder with key impairments in communication and social interaction and imagination (DSM IV, 1995) [72.268, 269]. Robots allow for a simplified, predictable, and reliable environment, where the complexity of interaction can be controlled and gradually increased [72.270]. Children can play dyadic games with robots, or triadic games involving other children or adults. In the latter case, scenarios emphasize the role of the robot as a *social mediator* or [72.271].

Robot mediated playing and learning activities, if successful, have the potential to enable children with cognitive disabilities to learn and acquire basic social skills thus getting support to develop/enhance their individual potential especially in the areas of communication and interaction [72.270, 272]. A number of different social robots have been studied in this domain, including zoomorphic robots, humanoid robots, or mechanically looking robots, e.g., Labo-1 [72.273], NAO [72.274], Probo [72.275], Robota [72.276, 277], Keepon [72.278], Aibo [72.279], Tito [72.280], KASPAR [72.21], and others. While we find encouraging results from case-study evaluations, further long-term and clinical studies are required [72.281].

Diehl et al. [72.281] in their review on the clinical use of robots for individuals with autism suggested that the use of interactive robots is a promising development in light of the research showing that individuals with autism exhibit strengths in understanding the physical world and relative weaknesses in understanding the social world. Children with autism often find it very difficult to appropriately interact with their social environment. In interactions between children and their peers, teachers, and family, usually touch has an important communicative and emotional role.

However, children with ASD may be hyposensitive or hypersensitive to touch so that the children may crave or avoid touch. As part of the above-mentioned Eu-

ropean Roboskin, a number of case study evaluations have been performed investigating how a humanoid robot equipped with touch sensors can teach children with autism about appropriate tactile interaction and the associated emotional responses. The studies used the child-sized, minimally expressive robot KASPAR [72.21]; [72.282]), a low-cost robot specifically designed for interaction – many of its features lend themselves to children with autism, e.g., the human-like but minimally expressive shape and form of the robot. The robot has 8 DOFs (degrees of freedom) in the head and face and 6 DOF in each arm, as well as one DOF in the torso. A comprehensive set of play scenarios for robot-assisted play for children with various special needs, and tactile play scenarios for children with autism have been developed [72.283–285].

KASPAR can play a variety of games with children, either operating completely autonomously [72.285, 286] and  VIDEO 220, or being partially remotely controlled by the children or an adult as part of the play scenario. Case studies on tactile child–robot interaction have shown encouraging results (*Robins* et al. [72.283, 287]). In the research on tactile interactions KASPAR was equipped with patches of tactile sensors, and it produced some responses autonomously, e.g., a ticking of the chest resulted in laughing, or hitting in the face results in the robot turning away from the child, covering its face with its hands and saying *ouch, that hurts*. If the child touches areas that are not covered by skin patches, or if the recognition of different types of touch is not reliable enough [72.288], then the experimenter can trigger the robot's reaction.

Figure 72.16 shows a child with autism first hitting the robot's leg and then exploring the robot's reaction. Since the legs cannot detect forceful touch, the experimenter triggers the robot's reactions. Note, this hybrid approach of autonomous behaviors combined with a remote control allows the robot to be perceptually more advanced than current state-of-the-art robotics sensing technology allows. Robots used with children with autism need to be predictable, and so a mistake in the robot's sensing abilities can be compensated for by the adult present (experimenter, teacher or caregiver). A person who knows the child very well will also be able to trigger certain useful robot behaviors at certain movements in time which are not observable directly from the child or the context and can only be inferred from detailed knowledge about the child, his/her needs and preferences, and therapeutic goals and objectives for this particular child.

Note, for a robot to detect and respond to tactile interactions of children with autism is not only beneficial to teach about appropriate tactile interaction, but it can

also provide a basis for adapting to a child's individual interaction style [72.265].

Tactile interaction is often not the sole focus of interaction, it can be embedded in multimodal play scenarios with the therapeutic objective to increase children's social skills through play. François et al. [72.279] present a long-term study where six children diagnosed with autism interact with an autonomous zoomorphic robot (Sony Aibo) over 10 sessions. The study is inspired by nondirective play therapy to encourage children's proactivity and initiative-taking. The behavior of each child is analyzed in detail according to three dimensions (play, reasoning, affect). Unique trajectories for children's progressions along these three dimensions were observed, resulting in unique profiles. The work highlights methodological issues in the domain of robot-assisted therapy, and also points out and formalizes different potential roles of the experimenter in the sessions, who may be a passive or an active participant [72.289]. A regulation process is introduced whereby the experimenter can regulate the interaction under specific conditions in order to:

1. Prevent or discourage repetitive behaviors
2. Help the child engage in play

3. Give a better pace to the game if it has already been experienced by the child
4. Bootstrap a higher level of play, and
5. Ask questions related to reasoning or affect.

72.8.4 Challenges and Opportunities

While many studies assume that tactile HRI will result in a more enjoyable, meaningful, and efficient interaction with a robot, many issues are still unclear and need to be investigated further. For example, a video-based study, where participants watched videos of interactions rather than interacting with the robot themselves, showed the impact of a robot's level of autonomy, and suggests that touch behaviors are considered more appropriate for proactive as compared to reactive robots [72.290]. Much further research is needed to find out when and how tactile interaction can enhance a person's experience of interaction and benefit the overall performance of the human-robot triads. One can also expect that individual differences will play a role in which types of tactile interaction with a robot are more appropriate, depending also on the tasks involved and the overall context and setting. The perception of people in terms of the robot's roles and its

Fig. 72.16 (a) Child hits the robot's leg and then explores the robot's reaction. (b) The child sees the robot looking sad, so he tickles its tummy (left) to make it happy (right). (c) The minimally expressive humanoid robot KASPAR

relationship with its users is also likely to impact these issues.

In recent years a number of projects worldwide have tried to use robots for therapy of children with autism. Different modes of robot control and autonomy need to be investigated, from fully autonomous systems [72.285], to Wizard-of-Oz controlled robots [72.291], to using a hybrid approach where remote control is an integral part of the interac-

tion and triggers autonomous behaviors [72.287, 289]. Realistically, for therapeutic tools to be used widely outside the laboratory and the experimental setting, the technology needs to be highly robust, reliable, easy to operate by nonresearchers as well as cost-effective.

A number of technological, methodological, and design challenges still need to be tackled, but tactile interactions with social robots open up a number of new research avenues as well as exciting applications.

72.9 Social Robots and Teamwork

Verbal and nonverbal communication play a very important role in coordinating joint action during collaborative tasks. Sharing information through communication acts is critical given that each teammate often has only partial knowledge relevant to solving the problem, different capabilities, and possibly diverging beliefs about the state of the task. For instance, all teammates need to establish and maintain a set of mutual beliefs regarding the current state of the task, the respective roles and capabilities of each member, and the responsibilities of each teammate [72.33, 153]. This is called *common ground* [72.162].

72.9.1 Human–Robot Teamwork and Collaboration

Dialog certainly plays an important role in establishing common ground. Each conversant is committed to the shared goal of establishing and maintaining a state of mutual belief with the other. To succeed, the speaker composes a description that is adequate for the purpose of being understood by the listener, and the listener shares the goal of understanding the speaker. This communication act serves to achieve robust team behavior despite adverse conditions, including breaks in communication and other difficulties in achieving the team goals.

Humans also use nonverbal skills such as visual perspective taking and shared attention to establish common ground with others. They orient their own gaze and direct the gaze of their teammate through deictic cues such as pointing gestures in order to establish common ground. Given the visual perspective taking, shared attention, and the use of deictic cues to direct attention are core psychological processes that people use to coordinate joint action about objects and events in the world, robot teammates must be able to display and interpret these behaviors and cues when working with humans in a manner that adheres to human expectations.

Breazeal et al. [72.142] investigated the impact grounding using nonverbal social cues and behavior on task performance by a human–robot team. In a human subject experiment, participants guided Leonardo to perform a physical task using speech and gesture. The robot communicates either implicitly through behavior (such as gaze and facial expressions) or explicitly through nonverbal social cues (i.e., explicit pointing gestures). The robot's explicit grounding acts include visually attending to the human's actions to acknowledge their contributions, issuing a short nod to acknowledge the success and completion of the task or subtask, visually attending to the person's attention directing cues such as to where the human looks or points, looking back to the human once the robot operates on an artifact to make sure its contribution is acknowledged, and pointing to artifacts in the workspace to direct the human's attention toward them. Both self-reporting via questionnaire and behavioral analysis of video support the hypothesis that implicit nonverbal communication positively impacts human–robot task performance with respect to understandability of the robot, efficiency of task performance, and robustness to errors that arise from miscommunication [72.142].

Common ground is grown along with partners that work together over time. In a simple example, if two persons repeatedly work in a sequence of collaborative manufacturing tasks, one will be able to easily predict what the other person will do next and thus proactively help each other. For instance, if one always needs a spanner to be passed at certain moment in the task, another person will probably take anticipatory action passing the spanner before being asked. *Hoffman* and *Breazeal* developed adaptive system that learn such task structure which enabled a robot's anticipatory action [72.292]. They further revealed the importance of perceptual simulation [72.293].

The importance of such common ground and cognitive similarity is demonstrated in partnership in casual social interaction too. For instance, *Morales* et al. re-

vealed that a robot efficiently performed side-by-side walking with a human partner when it anticipated where a human partner would walk [72.186]. Such anticipatory computing was enabled by a capability of computing a preferred walking course in a similar way as humans would do. There are robots that explicitly learn common knowledge, like one that learns names of places [72.294].

72.9.2 Robots as Social Mediators

Researchers have started to explore the use of robots as a *social mediator*. One approach is to use a human-like presence of robots as social stimuli. It is known that presence of people facilitate others. For instance, people perform simple math-calculation faster when being watched by someone else. This is known to be *social facilitation effect* [72.295]. Riethe et al. [72.296] reported that people's performance on easy math-calculation is improved because of presence of robots [72.296]. Takano et al. [72.297], put an android robot as a bystander where patients meet a medical doctor in a hospital, and found that it moderated clients' anxiety and let them believe that the doctor pays more attention to them [72.297].

Another approach is to use a robot as an active coordinator in humans' social settings. When there are many people, a coordinator could make their activity more efficient. Such a role can also successfully replicated by a robot. Consider the situation where an interactive robot is placed in the middle of a group of kids, and they start to push each other away when they want to play with the robot differently from each other. Shomi et al. [72.298], developed a technique to identify when crowd of people around a robot is disordered, and let the robot perform attention-controlling behavior so that children play together with the robot in coordinated way [72.299] (Fig. 72.17). In other work, robots have

Fig. 72.17 The robot interacted with a crowd of people with coordinating their attention

been used to facilitate elderly people's group conversation. Matsuyama et al. [72.300], developed a robot to participate in a quiz game, conducted as a recreation activity in elderly-care facility, and provide inspiring answer to facilitate other elderly people to continue the game [72.300]. In these works, robots actively model the social situation and intervene in people's activities based on its understanding of the situation.

72.9.3 Research Direction

Human activities are often social, involving multiple people who often have different skills, desires, and goals. Although the research is only in an early stage we have started to model such social situations while revealing potential roles of robots in such social settings. Along with further advance of relevant technologies, e.g., manipulation capability, navigation capability, and language capabilities, there should be many potential uses to be unveiled. However, it is most likely that the underlying theoretical work still needs a lot more work as well.

72.10 Conclusion

In this chapter, we have presented some of the principal research trends in social robotics and human-robot interaction. We have relied heavily on examples from our own research to illustrate these trends, and have used excellent examples drawn from other research groups around the world.

From this overview, we have shown that one of the most important goals of social robotics as applied HRI is the creation of robots that are human-compatible and human-centered in their design. Their differences from human abilities should complement and enhance

our strengths and support how people help one another. Their similarities to human abilities, such as computationally implementing human cognitive, affective, or multimodal communication models make them more intuitive for people to understand and interact with. Further, such robots are also being used as a scientific tool to help us to understand ourselves better. With this broadening understanding, social robots are being designed to offer increasingly sophisticated levels of social, affective, cognitive, and task-based support for people, opening new applications for robots

in education, health, therapy, communication, domestic tasks, physical tasks requiring coordination and teamwork, and more. As the field advances, social robots are being applied to increasingly sophisticated tasks, in increasingly complex human environments,

for longer deployment periods. We expect that in the coming decades, many other researchers, especially young researchers, will actively contribute to the transition from today's robots into capable robot partners of tomorrow.

72.11 Further Reading

For further reading, we recommend the following conference proceedings, journals, books, articles:

- Annual conference proceedings:
 - Proceedings of the ACM/IEEE International Conference on Human–Robot Interaction (HRI)
 - Proceedings of the IEEE International Symposium on Robot and Human Interactive Communication (ROMAN)
 - AAAI Symposium Series
 - AISB Symposium Series
- Journals:
 - Journal of Human-Robot Interaction (<http://humanrobotinteraction.org/journal/>)
 - Interaction Studies-Social Behaviour and Communication in Biological and Artificial Systems published by John Benjamins Publishing Company
 - International Journal of Social Robotics by Springer
 - IEEE Transactions on Autonomous Mental Development (TAMD)
 - IEEE Transactions on Human–Machine Systems
 - IEEE Transactions on Affective Computing
 - Paladyn, Journal of Behavioral Robotics, de Gruyter
 - PLoS ONE

Reviews and overviews can be found in several books and articles:

73. Socially Assistive Robotics

Maja J. Matarić, Brian Scassellati

This chapter reviews the critical societal issues that have motivated research into socially assistive robotics (SAR) (Sect. 73.2) and describes the reason why *physical robots* rather than virtual agents are essential to this effort (Sect. 73.3). It highlights the major research issues within this area (Sects. 73.4–73.7), describes the primary application domains and populations where SAR research has shown an impact (Sects. 73.8–73.11), and closes with some of the ethical and safety issues that SAR research necessitates (Sect. 73.12).

73.1 Overview

As robots become increasingly integrated into human environments, different forms of interaction are spawning new research topics and subfields. Human–robot interaction (HRI) can be broadly classified into two categories: physical and social/emotional. Physical HRI (Chap. 69) involves the research areas of manipula-

tion and haptics, among others, and is used in medical and rehabilitation robotics (Chaps. 63 and 64). In contrast, social/emotional interaction involves verbal and nonverbal expression and communication, and thus the research areas of assistive robotics, social robotics, and SAR.

Robots have long been used to provide assistance to individual users through physical interaction, typically by supporting direct physical rehabilitation (Chap. 64) or by providing a service such as retrieving items or cleaning floors (Chap. 55). Socially assistive robotics (SAR) is a comparatively new field of robotics that focuses on developing robots capable of assisting users through *social* rather than *physical* interaction. Just as a good coach or teacher can provide motivation, guidance, and support without making physical contact with a student, socially assistive robots attempt to provide the appropriate emotional, cognitive, and social cues to encourage development, learning, or therapy for an individual. SAR focuses on the challenges of providing motivation, coaching, training, and rehabilitation through nonphysical interaction; such systems have been validated in hands-off stroke rehabilitation, social skill training of children with autism, and eldercare, among others. In contrast, most of rehabilitation robotics focuses on physical interaction with the patient; such systems have been validated in hands-on stroke rehabilitation. Social robotics (Chap. 72) focuses on endowing robots with the ability to behave in socially aware and engaging ways; such systems have been validated

in museums, movies, classrooms, and informal settings. Service robotics can be seen as the overarching field that encompasses much of the work above.

A socially assistive robot is a system that employs hands-off interaction strategies, including the use of speech, facial expressions, and communicative gestures, to provide assistance in accordance with a particular assistive context. SAR systems equipped with motivational, social, pedagogical, and therapeutic capabilities have the potential to improve access to personalized care, training and rehabilitation to large populations, including individuals post-stroke, elderly, and children with social and developmental disabilities, in order to enhance their quality of life. An effective socially assistive robot must understand and interact with its environment, exhibit social behaviour, focus its attention and communication on the user, sustain engagement with the user, and achieve specific assistive goals. The robot must do all of this in a way that is safe, ethical and effective for the potentially vulnerable user. Socially assistive robots have been shown to have promise as therapeutic tool for children, the elderly, stroke patients, and other special-needs populations requiring personalized care.

73.2 The Need for Socially Assistive Robotics

The need for socially assistive robots is driven not only by rapidly growing populations that need additional assistance (including the elderly, individuals with cognitive disabilities, and individuals who require non-physical support during rehabilitation) but also by the recognition that social robots can have a substantial positive impact on personal challenges such as maintaining a healthy diet, supporting an active lifestyle, maintaining therapeutic programs, and supporting individualized education [73.1].

One of the most rapidly expanding populations requiring daily assistance is the elderly. The United Nations estimates that the population of those aged 60 and older will double in the next thirty years, with the elderly outnumbering children for the first time in history by 2045 [73.2]. Space and staff shortages at nursing homes and other care facilities are already an issue today. As the elderly population continues to grow, a great deal of attention and research will be dedicated to assistive systems aimed at promoting ageing-in-place, facilitating living independently in one's own home as long as possible. While many of these users will require some degree of physical assistance (such as standing up or carrying heavy groceries), many more are expected to require social and cognitive support to reduce isolation,

maintain active and healthy lifestyles, and to assist in daily therapy routines.

Individuals with cognitive disabilities and developmental and social disorders constitute another key growing population that can benefit from SAR in the contexts of special education, therapy, and training. Autism spectrum disorders (ASDs) have been the focus of much of the research in this area due to their prevalence, rapid growth of diagnoses, inherently social nature, and the critical need for long term, intensive treatment. Current research suggests that 1 in every 60 children in the United States will be diagnosed with ASD; the rate of diagnosis has increased sixfold between 1994 and 2003 [73.3]. The cause of the increase is not yet known. However, early intervention is critical to a positive long-term outcome, and many individuals need high levels of support and care throughout their lives [73.4–8]. Research into applying robots as therapy tools for ASD has focused on how to support repetitive, but necessary, social and behavioral therapies [73.9].

Motivation is recognized as the most significant challenge in physical rehabilitation and training [73.10]. SAR technology has the potential to provide novel means for monitoring, motivating, and

coaching. Post-stroke rehabilitation is one of the largest potential application domains, since stroke is a dominant cause of severe disability in the growing ageing population. In the United States alone, over 700 000 people suffer a new stroke each year, with the majority sustaining some permanent loss of movement [73.11]. Stroke patients frequently have difficulty with everyday functional movements and activities; the loss of function can be decreased through rehabilitation therapy during the critical post-stroke period. Such rehabilitation therapy involves carefully designed repetitive exercises, which can be passive and active. In passive exercises, the therapist (or a robot) actively helps the patient to repeatedly move the stroke-affected limb as prescribed. In active exercises, the patient does the work him/herself, with no physical assistance.

Finally, there is growing interest in using socially assistive robots to support an active and healthy lifestyle. These applications are again motivated by rapidly growing prevalence of obesity and a lack of effective interventions that are not labor-intensive. Childhood and adolescent obesity has been related to a host of adverse

proximal and distal health outcomes, including high cholesterol and triglycerides, hypertension [73.12], insulin resistance [73.13], type 2 diabetes [73.14], nonalcoholic fatty liver disease [73.15], as well as breast, colorectal, and other cancers [73.16]. Furthermore, childhood obesity sustains adverse consequences over the entire life span. In one review, all of the 25 longitudinal studies surveyed showed that overweight and obese youth were at higher risk of becoming overweight adults [73.17]. Per capita medical spending for an obese person is roughly 42% higher than for a person of normal weight [73.18] and outranks the health costs of both smoking and drinking alcohol [73.19]. Understanding, preventing, and treating childhood obesity is therefore a top public health priority [73.20]. Education about health impacts of obesity in addition to coaching and motivation for a healthy lifestyle are known to be effective means of lowering obesity rates [73.21]. **SAR** has the potential to play an important role in this context as an affordable and accessible means of providing personalized coaching, motivation, and training for exercise and healthy eating habits [73.22].

73.3 Advantages of Embodied Robots over Virtual Agents

Compared to virtual agents, robotic agents are typically more expensive, more difficult to replicate and distribute, more difficult to maintain and support, require a longer development time, and more fragile and susceptible to damage and system failure. In physically assistive tasks, virtual agent alternatives are not possible; manipulation of physical objects requires a physical presence. For socially assistive tasks, the added costs of a physical robot must be justified in comparison with a virtual agent solution.

73.3.1 Embodiment and Social Influence

One primary reason for using a physical robot in a socially assistive task is that robots can often exert more social influence over the user compared to a virtual agent. Socially assistive tasks often require the user to engage in tasks (such as therapy or homework) that are challenging and that the user might need encouragement or guidance to maintain. Multiple studies have demonstrated that physically embodied and collocated robots are more capable of generating the social presence to convince users to take these challenging steps. A physically present robot yields significantly more compliance to its requests, even when those requests are unexpected or unconventional, than a video representation of the same robot [73.23]. *Kidd* and

Breazeal [73.24] developed a table-top robot to serve as a daily weight-loss advisor; it engaged users through a touch-screen interface, tracked user progress and the state of the user-robot relationship over time, and was tested in a six-week field study with participants at home. The study compared the robot interactions against alternative weight loss methods, including using a standalone computer and maintaining paper logs, and found that participants exercised and tracked their caloric intake for nearly twice as long when interacting with the robot than with the other methods.

Interactions with physical robots are also more engaging and credible than virtual agents in cooperative task scenarios. For example, following a cooperative block-stacking task with a talking agent, participants found an agent more engaging, enjoyable, informative, and credible if it were a physically embodied robot, than if it were a virtually embodied animated character [73.24]. Other work has shown that after playing a cooperative game, people most enjoyed, and attributed the most watchfulness and helpfulness to a physically embodied robot than to a virtual embodiment (a graphical simulation) of the same robot [73.26]. *Bartneck* [73.27] conducted a study comparing the effectiveness of an emotionally expressive robot, *eMu*, with its screen character version in engaging users in a simple negotiation task, and found that participants

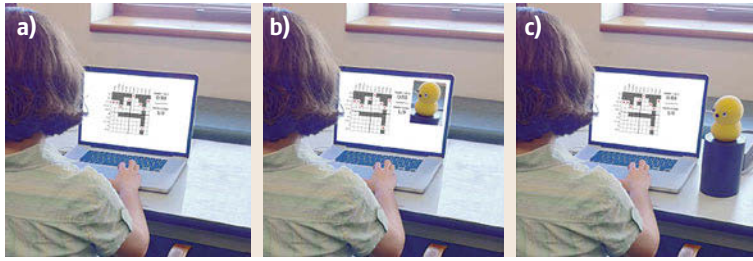

Fig.73.1a–c The physical presence of a robot tutor (c) has been shown to increase learning gains during a puzzle solving task substantially more than when the same tutoring lessons are delivered by a video of the same robot (b) or from a disembodied voice (a) (after [73.25])

exerted more effort and received higher task scores when interacting with the physical eMuu than with the simulated eMuu. Jung and Lee [73.28] also demonstrated the positive effects of physical embodiment in relation to interactions with both a Sony Aibo robot and an anthropomorphic dancing robot, April. Another study compared a physical co-present robot, to a remotely located one shown on the video screen, to a simulation of the same robot, all in the same interaction context; the study participants rated the co-present robot as more helpful, watchful, and appealing than remote and simulated counterparts [73.29]. These findings suggest that physical embodiment affords greater social attribution or enjoyment of an agent, than does virtual embodiment.

73.3.2 Embodiment and Learning

Physical robots have also been shown to enhance learning and impact later behavioral choice more substantially than virtual agents. Leyzberg et al. [73.25] showed that even when delivering the same lessons on solving cognitive puzzles, users improved their performance during a 20 min session almost twice as much when those lessons were delivered by a physical robot rather than by an on-screen video of the same robot. Kiesler et al. [73.30] used task performance measures to find that participants who received health advice from a physically present robot were more likely to choose a healthy snack than participants who received the same information in robot-video or on-screen agent conditions. Kidd and Breazeal [73.22] demonstrated that users were more likely to continue sessions with a robot weight-loss coach than with a virtual coach over a period of six weeks (Fig. 73.1).

73.3.3 Embodiment and Special Populations

While most of the investigations of the impact of physical embodiment on socially assistive tasks have been conducted with typical adults, embodiment effects have also been demonstrated on many of the particular populations that SAR projects typically target. Tapus and

Matarić [73.31] found that individuals suffering from cognitive impairment and/or Alzheimer's disease reported being more engaged with a robot treatment than a similar on-screen agent treatment. Numerous studies have demonstrated that children and adolescents with ASD engage readily with robots even when those children are unlikely to engage with animated characters on a screen [73.9, 32].

This impact of embodiment on preschool-age children has been of particular interest to educators and developmental psychologists. Although preschoolers learn from watching television and on-screen agents, many studies have focused on how learning and behavior shaping are more robust and generalize more readily when embedded in real time interactions with a physical agent:

1. Preschool children are multimodal learners, learning and retaining information better if there are overlapping modalities of experience [73.33–35].
2. Infants and preschool children off-load cognitive functions to the 3-D (three-dimensional) spatial structure of the world, for example, remembering the direction of attention rather than the content and then looking back to a location to re-perceive the content [73.36–38].
3. Children learn by physically manipulating and grouping objects [73.39, 40].
4. Preschool children learn from gross (whole body) movements; they do not have the fine motor skills to work in a limited spatial arena (such as a computer screen) and do not sustain attention when their gross motor activity is limited [73.41].

These facts suggest that learning and development will be best achieved in physical environments with physically realized teachers. Robotics may offer a mechanism to augment and support teacher–child and parent–child interactions.

Embodiment studies that have targeted the elderly population include the work of Heerink et al. [73.42], who investigated the acceptance of assistive social agents by older adults. The robot used in their evaluation was a table-top robot (the iCat), and was either controlled via a human operator during interaction with

elderly users (Wizard of Oz study), or interacted with users through a touch–screen interface. The interactions consisted primarily of short informational or utility interactions (e.g., medication/agenda reminders, weather forecast, companionship). *Fasola* and *Matarić* [73.43] also investigated the role of embodiment in a SAR exercise coach system, with a between-subjects study with participants split into two groups: physical robot coach versus virtual robot coach. Participants engaged in four exercise sessions over a two-week period, with each session lasting 20 min. The results of the between-subjects data analysis showed participants rated the physical robot significantly more positively than the virtual robot across all of the subjective measures, including enjoyableness and usefulness of the interaction, and also in terms of helpfulness, intelligence, social presence, and companionship of the robot coach. Direct comparison among the conditions also favored the physical robot significantly.

73.3.4 Evaluation of SAR Systems

One of the unique features of SAR is its evaluation process. All robotics requires the implementation of a physical system and its evaluation in the physical world, ideally outside of the laboratory setting, as close

to the intended final use as possible. In reality, however, the majority of research robots are evaluated in laboratory settings, because the alternative is prohibitive due to cost or access or both.

HRI puts the human in the loop and therefore requires evaluation with human users. Since human behavior is complex, it is not readily simulated. Consequently, SAR, which involves HRI, also requires evaluation with human users. However, to provide truly relevant and realistic evaluation for SAR systems, such systems must be tested with the intended populations, since testing with healthy adults is not appropriate for systems aimed at stroke patients, testing with adults is not appropriate for systems aimed at children, and so on.

Consequently, for a SAR approach to be truly evaluated, it needs to be tested with members of the intended end-user population, the more rigorously the better, according to the principles and best practices of human subject evaluations, as well as consistent with all the ethical rules associated with such procedures (Sect. 73.11). As a result, SAR development and evaluation can be time-consuming and requires multidisciplinary expertise that goes beyond robotics into social science and, as relevant, health science or education, among other disciplines.

73.4 Motivation, Autonomy, and Companionship

SAR systems equipped with motivational, social, and therapeutic capabilities have the potential to enhance user skills and quality of life. Motivation is a fundamental tool in establishing adherence to a training, rehabilitation, or therapy regimen and in promoting behavior change; therefore methods aimed at improving motivation are likely to be useful in the SAR contexts. There are two forms of motivation: intrinsic motivation, which comes from within a person, and extrinsic motivation, which comes from sources external to a person. Intrinsically motivated activities are those characterized by enjoyment [73.44]. Extrinsic motivation, though effective for short-term task compliance, has been shown to be less effective than intrinsic motivation for long-term task compliance and behavior change [73.45]. Intrinsic motivation, however, can be and often is affected by external factors, thereby offering a promising avenue for future SAR research. In a task scenario, for example, the instructor (or a socially assistive robot) can impact the user's intrinsic motivation through verbal feedback. Praise is considered a form of positive feedback and has the potential to increase the user's intrinsic motivation for performing the task, while criticism, a form of negative feedback, tends to negatively

impact the user's intrinsic motivation [73.46, 47]. The effect of positive feedback is closely tied to the user's own perceived competence at the task; once the user believes he is competent at the task, then additional praise no longer affects his intrinsic motivation.

Verbal feedback provided to the user by the instructor plays an important role in task-based motivation, but the task itself and how it is presented perhaps plays an even more significant role. *Csikszentmihalyi's* research suggests that [73.44]:

when one engages in an optimally challenging activity with respect to one's capacities there is a maximal probability for task-involved enjoyment or flow.

Therefore, an instructor that oversees user performance in a task scenario should also be aware of the user's current affective state or try to infer that state from task performance. The task must be continually adjusted to meet the appropriate needs of the user in order to increase or maintain intrinsic motivation to perform the task.

Another task characteristic with the potential to influence user enjoyment is the incorporation of direct

user input. Studies have shown that tasks that support user autonomy and self-determination lead to increased intrinsic motivation, self-esteem, creativity, and other related variables among the participants [73.48], all of which are essential for achieving task adherence and long term behavior change. Self-determination represented in the task such as choice of activity [73.49],

choice of difficulty level [73.50], and choice of rewards [73.51] have been shown to increase or be less detrimental to intrinsic motivation when compared to similar task conditions that do not involve choice. The positive impact of self-determination in task scenarios has also been supported by studies investigating behavior change [73.52, 53].

73.5 Influence and the Dynamics of Assistive Interaction

While social robotics has approached the issues of modeling the dynamic interplay of social interactions (Chap. 69), assistive interactions are unique among these social engagements as they must simultaneously support the needs of the engagement itself (by maintaining interest, novelty, and the conventions of social behavior) as well as guide the interaction toward the long-term behavioral or educational goals of the system. These two goals can often be in conflict; at times a good teacher (or coach, or socially assistive robot) must sacrifice some of the enjoyment of the interaction, or bend a social rule, in order to promote an educational goal. *Huang and Mutlu* [73.54] recently found some evidence that a robot could make some of these tradeoffs by changing its nonverbal behavior, focusing either on improving task performance (recall in a storytelling task) or on improving social engagement by varying the type of gaze behavior used by the robot.

Because the socially assistive robot must take an active part in shaping this interaction toward particular goals, the nature of the representations and the way in which this influence can be applied to shape the dynamics of the assistive interaction represents a core research question for **SAR**. Researchers address questions such as:

- What abstractions allow a robot to model the unique dynamics of a social interaction with a user in order to shape the user's behavior?
- Can we define a set of computational primitives that describe social roles, concepts, or properties in such interactions?
- Can this primitive set provide a basis of representations that allows robots to capture in real time the nuances of interaction, to shape and have their behavior shaped by that interaction, while allowing

generalization and comparisons across users, time scales, and contexts?

Much of the research in this area is based upon foundational psychological properties of human-human social interaction including agency, intentionality, causality, social roles, and goal attribution. These foundational elements discriminate between agents and objects, delineate which elements of the world can move with goal-directed purpose, and provide the primitive structure for describing cause and effect. If we are to build socially assistive robots, these systems must see the world in the same way that we humans do, in the same categories of animate and inanimate, and attribute cause and blame in the same way that we do.

Current computational models represent these features explicitly, with users overtly detailing their goals and intentions in an operationalized way [73.55]. In contrast, people are able to detect and analyze each other's agency and intentions *on line*, in a way that is often implicit, automatic, effortless, and even irresistible. To be successful, a socially assistive robot must understand, model, and engage in the dynamics of social interaction, so that computational systems can detect, analyze, and manipulate agency, intention, and other social primitives in dynamic environments in a way that is akin to how people do the same for social perception and behavior. These models must operate over a wide range of time scales and across input modalities (visual, auditory, tactile, etc.) and must be capable of interpreting and responding to social overtures in real time and with only minimal latency. Multiple studies have examined particular foundational aspects of the dynamics of interaction [73.56–58] as well as how persuasion might occur within those dynamics [73.59], but a complete model of the dynamics of social interaction remains one of the key research areas addressed within **SAR**.

73.6 Personalization and Adaptation to Specific Needs and Abilities

A second core research area for **SAR** concerns the personalization of the robot to the ever changing needs

and abilities of the user. While existing studies in social robotics often focus on a single matching process

by which the behavior of the robot is changed to optimize the properties of the interaction at a single moment in time, adaptation and personalization in assistive tasks should ideally treat the goal as an ever-changing target. As the assistive interaction is often sustained over substantially longer periods of time than other social robot interactions (lasting perhaps months or years), SAR systems should assume that the preferences, needs, and capabilities of the user change over the course of the interaction. Research in this area focuses on questions such as: How can we design a robot that adapts to each user's individual social, physical, and cognitive differences? How can a robot utilize patterns of interactions observed with other users (and possibly other robots) to bootstrap its own attempts at interaction? How do novelty and continuing personalization in interaction create and support trust, learning, and adaptation for improved outcomes for its user?

Socially assistive robots could greatly benefit from adapting to each individual user's unique social, cognitive, and physical abilities. Computationally, the challenge in constructing such a system stems from the individual differences among users and adaptation must occur at multiple levels of abstraction and time scales. At a given moment, robot responses that one user might find frustrating might be optimally engaging to another,

or even to the same user under different conditions or at different times. Their responses should also change over time as the user becomes tired, frustrated, or bored. Responses must also vary from session to session or day to day so that interactions remain engaging and interesting.

Very little research to date addresses learning through personalized social interaction [73.60], especially with populations like children, the elderly, or individuals with social and cognitive deficits. Various learning approaches for HRI have been proposed [73.61], but to date, none have included the user's profile, preferences, and/or personality. The robot's capability to adapt to an individual user's needs and abilities must be bounded by the social and cultural context and while filling the role of a supportive partner or peer. The majority of current machine learning methods are focused on learning specific policies or parameters for tasks or behaviors. While there is a plethora of available learning methods, and some are particularly relevant to SAR, such as user state and activity modeling [73.62, 63], learning by imitation and from demonstration [73.64–68], and learning interaction models from crowd-sourced interaction [73.69], no work to date has focused on adapting to individual differences.

73.7 Creating Long-Term Engagement and Behaviour Change

The ultimate objective for any socially assistive robot is to alter the long-term behavior of the user in line with the behavioral, therapeutic, or educational goals that the robot was designed to support. For many of the application domains covered by SAR systems, this change might require months or years of interaction. A critical research issue for SAR is the development of systems that can maintain these long-term social interactions, monitor the behavioral changes of the user over these long-term interactions, and promote activities that support selective changes in behavior.

Research questions related to this area include: How can a robot continue to be interesting and engaging to a user over an extended time period? What social behaviors and attributes are needed to establish and sustain trust, rapport, and comfort with the user over time to build a successful relationship that continues to provide value? How can a robot continue to adapt to and autonomously guide its user through successive milestones in order to achieve desired learning or behavior change outcomes over longitudinal time scales? What strategy should a robot employ to motivate and maintain lessons or activities, and how should this strategy evolve over time? How can the robot recognize when

its goals related to the behavior change of the user have been achieved, or when intermediary goals have been achieved?

To better fill the social role of supportive partners, socially assistive robots should adapt their behavior and actively planning the trajectory of interactions to guide users toward learning or behavioral goals. The ability to adapt and plan should be demonstrated at multiple time-scales and abstraction levels so as to enable long-term engagement over days, weeks, months, and eventually years. Such capability is particularly important for special populations who may have different responses to techniques and methods that are often employed with typical adults. Almost no work to date has focused on the computational challenges involved in creating social interactions that persist over multiple weeks, months, or years. Early efforts in the area of life-long learning still operate on short time-scales (e.g., two or three cases/tasks) compared to the weeks and months that will be necessary for SAR systems. This particular goal presents a myriad of interesting and challenging applications of complex computational methods such as machine learning. Socially assistive robots capable of long-term adaptation must constantly

sample new interaction and teaching strategies while exploiting previously learned preferences of each individual user and between users, all in an online setting. Extending engagement, social support, and guidance to long-term interaction requires more than scaling

up existing methods and measures. A major scientific goal for SAR research is to develop new insights that enable long-term adaptive support and guidance to the user in order to sustain a productive assistive relationship.

73.8 SAR for Autism Spectrum Disorder (ASD) Therapy

Some of the earliest and most extensive investigations of SAR have focused on the diagnosis and treatment of autism spectrum disorders. Driven by pressing needs from a rapidly expanding population and remarkable early results, a diverse set of robotics research groups have examined the responses of individuals with autism spectrum disorders to robots [73.9, 32].

73.8.1 Summary of ASD-Related Challenges

Autism is a pervasive developmental disorder marked by severe deficits in social functioning such as difficulties recognizing body language, making eye contact, and understanding the emotions of other people [73.4]. It is typically associated with a range of cognitive and attentional deficits [73.70, 71] as well as tendency to engage in preservative and self-stimulatory behaviors. Expression of particular behaviors is highly heterogeneous and associated with notable intra-individual variation in the level of functioning in specific domains. That is, while some children have exceptional cognitive skills, others struggle with major challenges in these areas.

ASD has received a heightened interest from researchers in recent years due to, in part, an unprecedented increase in the incidence rate. ASD is estimated to affect one in every 60 children in the United States, a rate that is roughly eight times higher than the best estimates from 20 years ago [73.72]. ASD is a behaviorally specified disorder [73.5]; there is no blood test, no genetic screening, and no functional imaging test that can diagnose ASD. Diagnosis relies on the clinician's intuitive feel for the child's social skills including eye-to-eye gaze, facial expression, body postures, and gestures. These observational judgments are then quantified according to standardized protocols [73.6, 7, 73, 74] that are both imprecise and subjective. The broad disagreement of clinicians on individual diagnoses creates difficulties both for selecting appropriate treatment for individuals and for reporting the results of population-based studies [73.8, 75].

ASD is a lifelong disorder; there is no known cure. However, early, sustained, and intensive intervention

using a variety of behavioral techniques have been demonstrated to produce substantive gains in many individuals with ASD [73.5]. These therapeutic approaches often focus on traditional behavioral therapies in which a skilled therapist guides an individual with ASD through a series of repetitive exercises aimed at improving daily living and/or functional social skills. These techniques require a tremendous amount of labor, and attempts to use technological innovations to alleviate some of this burden have been a popular research topic. For example, pet-assisted therapy [73.76, 77], computer-assisted therapy [73.78–80] and virtual reality-based approaches [73.81, 82] have all been studied. While these have shown some success, there has been limited investigation of the parameters of the conditions necessary to generalize the benefits to interactions with human partners. Among nonhuman partners, robots that provide instruction, support, and assistance through social interaction have been seen as a potential mechanism for supporting therapy and daily living for individuals with ASD [73.1, 83].

Robots promise unique practical advantages over other nonhuman interactive partners. First, they can potentially provide identical delivery of stimuli, establishing a uniquely high level of control in diagnosis and assessment [73.83]. Second, they do not require the months or years of training that animal assistants may need, as robots can be designed to allow flexible customization. Third, they offer a potential for tactile interface and the immediacy of embodied agency, which computer programs and virtual realities cannot provide. In cases in which human or animal therapeutic aids may be unavailable or are prohibitively expensive, and where software or virtual reality therapeutic tools cannot provide sufficient embodiment, robots may provide an especially useful addition to therapy.

73.8.2 User Study Insights

Research in this area has shown exciting, but often preliminary, benefits to individuals with ASD, including increased engagement in tasks, increased levels of attention, and novel social behaviors such as joint attention and spontaneous imitation, when robots are part of

the interaction [73.83–89]. Much of the early work in this domain was exploratory, performed on small sample sizes (typically fewer than 5 individuals), lacked quantitative measurements of success, failed to include a control group, and had minimal diagnostic and inclusionary criteria. Given the heterogeneity of ASD, these exploratory studies were frequently dismissed by the clinical research community. These exploratory studies however were instrumental in laying the groundwork for the more extensive and detailed studies that are being performed today [73.9].

More recent studies have focused on how robots can enhance human-to-human social behavior in children with ASD and have included statistically valid sample sizes, carefully designed control conditions, and extensive diagnostics to accurately describe the population being studied. For example, *Kim et al.* [73.90] recently demonstrated a robot that engaged children in a vocal prosody training task. Children with ASD were more likely to use appropriate inflection in their voices when engaging the robot than when interacting with a familiar clinician. Furthermore, some children in this study demonstrated increased frequency of social gaze behaviors to an adult (including social referencing) immediately following interaction with a social robot. *Feil-Seifer and Matarić* [73.91] recently demonstrated that children with ASD demonstrated an increased social response to a robot that was socially responsive than to one that was not. The study included a comparable toy as a control and its results included novel insights about child–robot interactions for verbal and nonverbal children with ASD (Fig. 73.2,73.3).

73.8.3 Research Directions

While these *HRI* studies offer the hope of a novel therapeutic approach, they have to date neither explained why robots provoke these responses in children nor demonstrated that a long-term behavioral change in children can be generated that generalizes to human–human interactions. A number of possible hypotheses could explain the increase in social behavior observed

Fig.73.2a,b Both highly anthropomorphic robots ((a) Kasper from the University of Hertfordshire) and highly mechanistic robots ((b) Bubblebot from the University of Southern California) have shown increased social responses of children with ASD during interactions with robots

during and after interactions between an individual with ASD and a robot. Perhaps robots offer a more predictable interaction, or a more selective and simplified set of social cues to be interpreted, or are more overt in their behavioral responses and easier to engage in reciprocal interactions. There is anecdotal evidence that some of these may not be a satisfactory explanation [73.83,90], but a robust explanation of why these effects are so notable in interactions with individuals with ASD has yet to be described.

Constructing autonomous systems is particularly challenging for this population. The diversity of abilities and deficits within the ASD population results in vast differences in the rate of interaction, the mode of interaction (e.g., verbal versus nonverbal), the social skills to be included in the training, and even the criteria for what constitutes a successful application of a social skill [73.32]. While a few studies [73.92] have begun to incorporate completely autonomous systems, most are still utilizing wizard-of-Oz techniques to deal with the variations across users.

Perhaps the most clinically important research direction is to establish that *HRIs* provide a long-term, measurable change in human–human interactions. Nearly all of the studies carried out to date (with the exception of [73.87]), focus on a small number of short interactions (typically spanning a combined time of less

Fig.73.3a–c *Kim et al.* [73.89,90] demonstrated increases in child–adult interactions following a short (5 min) interaction with a robot. These images come from video captured before (a), during (b), and after (c) an interaction with a Pleo robot, which focused on prosodic production

than an hour). As behavioral change even with an expert clinician can require hundreds of hours of training, our research studies must extend to more lasting interactions that span weeks and months. Furthermore, most studies to date focus on the development of social behaviors directed at the robot. These robot-directed behaviors have minimal clinical value unless they can be shown to generalize to human–human interactions.

(One exception is the studies by *Kim et al.* [73.89, 90] which demonstrated that children with ASD show a significant improvement in face-to-face interactions with an adult immediately following an interaction with a robot tutor). To provide therapeutic value to an individual with ASD, interactive robots must provide either a measurable benefit to their ability to engage with other people.

73.9 SAR Supporting Rehabilitation

SAR is especially well suited for use in the process of rehabilitation, which involves regaining function lost due to illness or trauma. Where rehabilitation robotics focuses on hands-on **HRI**, in contrast, **SAR** focuses on providing motivation and coaching in order to facilitate the rehabilitation process. Since motivation has long been recognized as a major factor in rehabilitation, **SAR** has the potential to play a key role in this health context. **SAR** systems for supporting rehabilitation have been developed and tested with stroke patients [73.93, 94] and Alzheimer’s patients [73.95], and are being considered for use in traumatic brain injury rehabilitation.

73.9.1 Summary of Rehabilitation Challenges

Stroke is the leading cause of serious, long-term disability in the US and the third leading cause of death [73.96]. In the US alone, over 800 000 people suffer a stroke each year, and nearly 400 000 survive with some form of neurologic disability [73.97]. The number of stroke survivors with disability is expected to double by the year 2025 [73.98]. Over 80% of first-time strokes involve loss of function of the upper limb that significantly impacts the independence and health of the stroke survivor [73.99–101]. The residual disability after stroke is substantial, with over 65% of patients unable to incorporate the affected hand effectively into daily activities. Functional recovery of the arm and hand has generally been resistant to the traditional approaches of stroke rehabilitation compared with that for the lower extremities program [73.99, 102].

Stroke often leaves individuals unable to perform movements with the affected limb even though the limb is not completely paralyzed. This loss of function, termed *learned disuse*, can improve with rehabilitation therapy [73.103, 104]. Clinical studies using motor training have found improvement in functional upper limb performance in patients more than one year post stroke and cortical reorganization and recruitment of adjacent brain areas associated with intensive use of

the affected upper limb have been documented several years after the initial stroke injury [73.105–107]. Repetitive, intense, task-specific practice is effective in rehabilitation [73.108–111]. Indeed, practice is fundamental to motor learning – it is the single most important variable for skill acquisition. However, such practice requires trained coaching and motivation.

73.9.2 Contact Versus SAR (Noncontact) Robotics for Rehabilitation

SAR creates a bridge between rehabilitation robotics, which has historically been contact-based [73.112, 113], with noncontact functionalities, such as companion robotics [73.114, 115]. The noncontact approach defines a key niche for **SAR** that involves an autonomous physically embodied robot providing contact-free monitoring, coaching, and encouragement, while also providing detailed assessments of client progress to key stakeholders including and importantly the user. Unlike rehabilitation robotics, where the application and perception of forces are the main focus, and which are consequently currently limited to in-clinic settings, work with noncontact robots is instead directed at the interaction modalities and motivation strategies for achieving specific goals in the home and community settings.

One of the most important elements of any rehabilitation program is the practice of carefully directed, well-focused and repetitive exercises, which can be passive or active. In passive exercises (also known as hands-on rehabilitation), the patient is helped by a human (or robotic) therapist to appropriately exercise the affected limb(s). In contrast, in active exercises, the patient performs the exercises with no physical assistance. The majority of existing work in rehabilitation robotics focuses on hands-on robotic systems for passive exercise, focusing on attempting to recover upper-limb function primarily through robotic manipulation of the affected-limb. *Burgar et al.* [73.116] developed a robot-assisted arm therapy workstation, in which patients

can exercise their upper limbs and evaluate their performance. A similar device, which also depends on hands-on robotic technology, was developed by *Krebs et al.* [73.117]. Other related systems have been investigated [73.118] and [73.119]. Because human-robot contact involves complex issues of safety, such hands-on robotics methods remain areas of active ongoing research, with many outstanding challenges. Currently, contact rehabilitation robots are not portable; the logistics of contact robot therapy are further limited by cost, availability of adequate amount of practice, expertise necessary to program and execute trials, and liability. Risk of injury to the patient is of concern when movement of a limb with sensorimotor loss is imposed by a robot [73.120, 121]. Finally, intense functional exercise is more likely to sustain the behavior (upper limb functional use) in the long term in contrast to the decline in long-term performance with contact robot systems after therapy has ceased [73.120–122].

The **SAR** system acts as a *coach*, providing encouragement, and direction, and ensuring proper adherence with the therapy regimen. Given the size of the stroke-affected population and the time-intensive personalized requirements, such coaching is not possible with human therapists, creating a niche for technological means of filling the gap. By providing the opportunity for time-extended monitoring and encouragement of rehabilitation exercises in any setting (at the clinic or at home), **SAR** systems complement human care [73.123–126].

73.9.3 User Study Insights

This section reviews some of the insights from **SAR** studies performed with stroke patients. One study [73.93, 127] focused on how different robot behaviors may affect the patient's willingness to adhere to the rehabilitation program. The study evaluated different voices, movements, and levels of patience on the part of the robot, and correlated those with patient adherence. The robot was equipped with navigation capabilities, so it could find and follow the patient, maneuver itself to an appropriate position for monitoring the patient, and leave when it was not wanted. The robot acquired real-time information about the patient's use of the stroke-affected limb from inertial measurement unit (**IMU**)-based sensors worn by the patient. Wearable sensors present an important alternative to machine vision, which may not be acceptable to all users due to privacy concerns. The robot used information provided by the wearable sensors to encourage the patient to continue using the limb, or to use the limb more or in a different way, as appropriate. The robot was well received by the patients. Some continued to perform the

activity beyond the end of the experiment, providing further evidence of improved adherence well beyond any novelty effects. As expected, there were significant personality differences among the patients; some were highly adherent but appeared un-engaged by the robot, while others were highly engaged and even entertained, but preferred to interact with the robot rather than perform the coached exercises. This leads toward interesting research questions of how to define adaptive robot-assisted rehabilitation protocols that will serve the diverse user population as well as the time-extended and evolving needs of every individual user.

Modeling personality in order to customize **HRI** has a particular relevance to stroke rehabilitation because pre-stroke personality has a great influence on post-stroke recovery [73.96]; individuals classified as extroverted before the stroke mobilize their strength more easily to recover than do introverted subjects [73.128]. Further, work in human-computer interaction (**HCI**) has demonstrated the similarity-attraction principle, which posits that individuals are more attracted to others manifesting the same personality as theirs [73.129–131]. *Tapus* and *Mataric* [73.132] performed a **SAR** study to test related effects. In a series of experiments with a simple mobile robot equipped with a camera and a microphone, participants were asked to perform four tasks (designed as functional activities) similar to those used during standard stroke rehabilitation. The participants completed a personality assessment questionnaire before the experiment; the resulting personality based specifically on the extroversion-introversion dimension was used to determine the robot's personality. The behavior control architecture was based on the model of reciprocal influences on behavior [73.133]. The robot expressed its personality through several means: (1) proxemics (social use of space; extroverted personalities used smaller personal distances) [73.134]; (2) speed and amount of movement (extroverted personalities moved more and faster); and (3) verbal content (extroverted personalities talked more assertively (*You have done only x movements, I'm sure you can do more!*), using a challenge-based style compared to a nurture-based style (*I know it's hard, but remember it's for your own good.*)). The experiment compared personality-matched versus personality-mismatched (random) conditions. The results showed that the robot's personality was fundamental to the quality of the interaction. Two statistically significant results were found: (1) participants consistently performed better on the task when interacting with the personality-matched robot; (2) participants reported preferring the personality-matched robot. *Tapus et al.* [73.94] then expanded on this work by enabling the **SAR** system to adapt its personality based on the past interactions with the user.

Fig.73.4a,b Seated exercise coaching with a socially assistive humanoid robot on wheels, (a) Bandit, from the University of Southern California, and (b) upper extremity rehabilitation manipulation

Formulated as policy gradient reinforcement learning (PGRL), the adaptation allowed for optimizing the interaction parameters: interaction distance/proxemics, speed, and verbal content (what the robot says and how it says it). The learning algorithm was initialized with parameter values that were in the vicinity of what was thought to be acceptable for both extroverted and introverted individuals, based on the user–robot personality matching study described earlier. Gradual adaptation around a solution rather than random probing of the solution space is important; if the robot’s initial personality is far off the mark, or if it changes drastically, users are dissatisfied with the interaction. The results provided evidence for the effectiveness of robot behavior adaptation to user personality and performance: users tended to perform more or longer trials under the personality matched and therapy style-matched conditions (nurturing styles were correlated with the introversion, and challenging styles with extroversion).

Another study with stroke patients compared matched humanoid robot and simulated agent implementation of the SAR coach. The study participants were seated at a desk, and were asked by the robot to move magazines from the lower to the higher rack and to de-shelf as many magazines as possible in 6 min. The robot monitored the participant’s motions using a revised version of the motion sensors described above [73.135, 136]. The participants could use the button on a WiiMote to stop the interaction at any time. The IMU data and shelf state (using a scale) were used to classify the movement into states of progress (e.g., resting, picking up magazine, lifting arm, shelving book, lowering arm). In addition to the verbalizations, the robot used *beat gestures* whenever it spoke. This consisted of moving the head, arms, and hands in a beat with amplitude and frequency governed by the characteristics of the phrase that was being uttered. Baseline

movement data were assessed using standard stroke movement tests and task improvement was measured after repeated sessions. The experimental design involved all participants experimenting with both the robot and the computer. Two-thirds of the participants preferred the physical robot, with one third having no preference.

73.9.4 Research Directions

SAR for rehabilitation presents multi-faceted research challenges.

Personalizing the interaction to adapt to the user’s changing state over multiple timescales remains a major challenge, since rehabilitation aims for long-term improvement, but must contend with mood, fatigue, and performance variations within each session, as well as short term trends that may plateau or even reverse. Personalizing the interaction thus requires new ways of integrating robot learning, user modelling, and motivation strategies, among many other SAR research challenges. Creating robotic systems capable of adapting their behavior in order to provide an engaging and motivating customized protocol is a challenging target, especially when working with vulnerable user populations. In the SAR context, behavior adaptation must address both short-term changes that represent individual differences and long-term changes that allow the interaction to continue to be engaging over a period of months and even years. Various learning approaches for HRI have been proposed in the literature [73.61, 65] but this remains a major challenge in robotics in general and in SAR in particular.

Modeling the user and predicting user behavior is a challenge common to HRI and HCI, as well as research in signal processing and related fields. However, SAR also brings up the issue of modelling the identity of the robot character. Specifically, studies in SAR are beginning to show that having not only a personality but also a back story for the robot facilitates user engagement.

Research into relational agents [73.137] has been applied to short-term interactions in medical settings, such as hospital checkout procedures. Some of the insights from that field, including politeness theory, empathy, etc., are being explored in SAR for use in long-term interactions involved in rehabilitation.

Finally, one of the much needed new directions of research is the exploration of bringing together contact and noncontact rehabilitation robotics in relevant domains, in order to enhance the impact of both robotics subfields.

73.10 SAR and Eldercare

73.10.1 Summary of Eldercare Challenges

The growing population of aging adults is increasing the demand for healthcare services worldwide. By the year 2050, the number of people over the age of 85 will increase threefold [73.138], while the shortfall of nurses and caregivers is already an issue [73.139–141]. Regular physical exercise has been shown to be effective at maintaining and improving overall health [73.142–145]. Physical fitness is associated with higher functioning in the executive control processes [73.146] and is correlated with less atrophy of frontal cortex regions [73.147] and with improved reaction times [73.148]. Social interaction, and specifically high perceived interpersonal social support, has also been shown to have a positive impact on general mental and physical wellbeing [73.149], in addition to reducing the likelihood of depression [73.150–153]. Thus, the availability of physical exercise therapy, social interaction, and companionship will be critical for the growing elderly population.

The probability for acquired motor, cognitive, and perceptual disabilities dramatically increases with age [73.154]. Over 50 million Americans have a disability that affects one or more of their major life activities [73.155, 156] and only 30% are employed [73.157]. The economic cost of the associated loss of functioning is high; e.g., the cumulative total of stroke-affected Americans is over 4 million, and the estimated annual burden from stroke-related disability is \$53.6 billion, of which \$20.6 billion is in indirect costs due to lost productivity and income [73.96, 158]. Given projections that the number of people older than 65 years is anticipated to double between 1997 and 2025 [73.156] and that 30% of the population will be over 65 [73.159, 160], we will soon face new major technical and social challenges to attain, prolong, and preserve quality of life.

A especially vulnerable and sizeable population consists of individuals who are aging with disabilities that were acquired at any stage of life, from birth or early in life to stroke or other disorders later in life [73.161]. The number of middle aged and older adults living with disabilities will grow significantly as the U.S. population ages rapidly [73.162]. People who have managed their lives very successfully for years may find that they are experiencing the effects of aging earlier than others or are developing secondary health conditions as they reach their 30s or 40s [73.163, 164]. As persons with disabilities age, progressive declines in health and medical status can challenge the adaptive resources required to maintain functional independence and quality of life [73.165, 166].

Motor and cognitive dysfunctions that accompany chronic illness and disability in late life are major precursors for people who age into disability. Cognitive impairments are associated with increased disability in aging populations [73.167]; 19% of women and 13% of men aged 65–69 live with a disability in mobility [73.168]. The respective percentages increase to 83% and 63% for women and men aged 90–95 [73.168]. These dysfunctions greatly compound the disruptions in overall lifestyle and occupational status experienced by individuals aging with disabilities primarily associated with cognitive or motor deficits. Thus, there is a critical need to develop effective and affordable assistive technologies to improve the motor and cognitive functioning, especially in individuals aging with disabilities. This creates an important niche for SAR.

73.10.2 User Study Insights

The literature that addresses assistive robotics intended for and evaluated by the elderly is limited but growing.

Researchers have investigated the use of robots to help address the social and emotional needs of the elderly, including reducing depression and increasing social interaction with peers. Wada et al. [73.114] studied the psychological effects of a seal robot, Paro, used to engage seniors at a day service center. The study found that Paro, always accompanied by a human handler, was able to consistently improve the moods of elderly participants who spent time petting and engaging with it over the course of a 6-week period. Kidd et al. [73.115] used Paro in another study that found it to be useful as a catalyst for social interaction. They observed that seniors who participated with the robot in a group were more likely to interact socially with each other when the robot was present and powered on, rather than when it was powered off or absent.

Social agents that aim to assist individuals in health-related tasks such as physical exercise have also been developed in the HCI community. Bickmore and Picard [73.137] developed a computer-based virtual relational agent that served as a daily exercise advisor by engaging the user in conversation and providing educational information about walking for exercise, asking about the user's daily activity levels, tracking user progress over time while giving feedback, and engaging the user in relational dialogue.

Fasola and Matarić [73.169] conducted a study to investigate the role of praise and relational discourse (politeness, humor, empathy, etc.) in a SAR exercise

Fig.73.5a–c Paro robot (a) from the University of Tokyo, Autom robot (b) used in an MIT weight-loss study, and Healthbot robot (c) from the University of Auckland used in a large-scale elderly care study

system designed for older adults. The study compared a relational robot versus a nonrelational robot. The relational robot employed praise and relational discourse, while the nonrelational robot guided the exercise interaction without such praise or discourse. Results showed participants rated the relational robot significantly more positively than the nonrelational robot in terms of enjoyableness and usefulness of the interaction, and as a companion and exercise coach. *Fasola and Matarić* [73.169] also conducted a user study to investigate the role of choice and user autonomy within

the same SAR exercise system. The results of the study showed no clear preference for one condition over the other, as the user enjoyment level of the interaction was reported to be equally high for choice and no-choice conditions. This suggests that a hybrid approach that includes both user and robot decision making, personalized and tuned automatically for each user, might ultimately be the best solution for achieving a fluid and enjoyable task interaction for all users. This once again underscores the need for personalized methods of HRI and user modeling and adaptation.

73.11 SAR for Alzheimer's Dementia and Cognitive Rehabilitation

Dementia is a progressive disabling neurological condition that can be a symptom of several diseases, including Alzheimer's, which makes up about half of all cases of dementia. The latest estimate is that 26.6 million people were suffering from Alzheimer's disease worldwide in 2006, and it will rise to 100 million by 2050 – 1 in 85 of the total population [73.170]. More than 40% of those cases will be in late-stage Alzheimer's, requiring a high level of attention equivalent to nursing home care. Individuals suffering from Alzheimer's experience a decrease in verbal and cognitive skills along with the deterioration of strength and flexibility that comes with aging. Rehabilitation therapies for individuals with dementia often focus on both cognitive and motor exercises to in order to preserve patients' autonomy for as long as possible.

Therapy for individuals with dementia must be pervasive and ongoing in their everyday lives. Mental and physical exercise involving art, music, and playing with/tending to animals have been used to preserve cognitive function in older adults who have begun experience symptoms of dementia. However, these therapies can only be offered by well-trained personnel. In particular, animal therapy can involve safety risks for both the animal and the patient. The goal of SAR in this ther-

apy context is to provide a means of providing therapy that is safe, easy to use, and does not require special training.

73.11.1 User Study Insights

In a study by *Tamura et al.* [73.171], an entertainment robot was used as occupational therapy instead of animal-assisted therapy to avoid any danger or injury to the patient and maintain cleanliness. The study compared the effectiveness of a robot animal, AIBO, with a toy. AIBO responded to spoken commands and was demonstrated to severely demented elderly people living in a geriatric home. The most frequent reactions to AIBO consisted of looking at, communicating with, and caring for the robot. The patients recognized that AIBO was a robot but, once the robot was addressed by the experimenters, the patients perceived it as either a dog or a baby. The presentation resulted in positive outcomes for the severe dementia patients, including increased communication between the patients and the robot.

Tapus et al. [73.172] performed a long-term (6-month) study of socially assistive robots in the context of cognitive training for Alzheimer's patients to test if

elderly individuals with Alzheimer's impairments can maintain attention to music with the help of a SAR system. A small group of four participants over 70 years old, suffering from mild to severe cognitive impairment and/or Alzheimer's disease, took part in the study and received pre- and post-study cognitive assessments. Each interacted in one-on-one twice-weekly sessions with the robot, in which the robot presented a music recognition game with three different levels of challenge: difficult (no hints), medium (hints given), and easy (name of song given). The challenge level was adjusted to each participant based on performance. The results obtained over 6 months of robot interaction (excluding the 2 months of learning) suggest that elderly people suffering of dementia and/or Alzheimer's can sustain attention to music across a long period of time and even improve on the music recognition task when coached by a socially assistive robot; the SAR system was able to adapt the challenge level of the game it was presenting to the user in order to encourage task improvement and attention training. Importantly, the participants demonstrated fondness for the robot and included it into their daily narratives (e.g., *My buddy is coming to visit, I don't want to miss it.*).

The multiyear Healthbots project at the University of Auckland is examining the role of telepresence and humanoid robots in assisted living communi-

ties [73.173]. This large study included three different types of robots, ranging from large telepresence to small humanoid, which were deployed as companions and nursing assistants in a retirement village of around 650 residents. Several insights were gained from the long-term deployment, including the preferences of both the elderly users and staff members. The most promising avenue for robotic assistance was a robot that was sent into residents' rooms to remind them to take their medications or fetch them for appointments.

73.11.2 Research Directions

As with all areas of SAR, the user's willingness to engage with a socially assistive robot to accept advice, interact, and ultimately alter behavior depends on the robot's ability to obtain the user's trust and sustain the user's interest. User interfaces and input devices that are easy and intuitive for a range of users, including those with special needs, need to be developed. Social interaction is inherently bidirectional and thus involves both multimodal perception and communication, including verbal and nonverbal means. Toward that end, automated behavior detection and classification as well as activity recognition, including user intent, task-specific attention, and failure recognition, are critical enabling components being developed.

73.12 Ethical and Safety Considerations

SAR, with its focus on developing human-robot relationships and influencing human behavior, naturally brings about several distinct types of ethical considerations.

Safety of the user is the first and most obvious consideration in any area of HRI. Because SAR systems do not involve physical contact initiated by either people or robots, they present a minimum of physical safety issues. However, while physical safety is one of the largest concerns in other areas of robotics research (Chap. 30), in SAR, emotional and other types of non-physical safety must be considered.

As SAR research strives to achieve user engagement and attachment, some critics have argued that such relationships should be reserved for humans only [73.174]. Evaluations of specific SAR systems have triggered ethical dilemmas [73.174, 175]. Turkle [73.174] demonstrated that some participants interacting with robots can correctly identify the robot's intended emotional abilities and operational capabilities. These participants could also correctly distinguish equivalent capabilities in a person, pet, or other relational artifact. However, it

was also demonstrated that some users formed attachments and emotional bonds with robots they were interacting with. These attachments led to misconceptions about the robots' emotional capabilities. For example, one user felt that the robot would miss him when he was gone, something that the robot was not capable of doing. Sharkey and Sharkey [73.175] argue strongly that such attachments in children could lead to malformed development and emotional problems. Some such arguments are based on the notion that human care is replaced by robot care, which is not consistent with the premise of most of SAR research. Most SAR research clearly state that their aim is to *augment rather than replace human care*, as discussed in Sect. 73.7 of this chapter, in the context of SAR for autism spectrum disorders.

Some more pragmatic ethical considerations take into account the inevitable progress of technology, which will render any particular system obsolete well within a user's lifetime, therefore undermining attachment and likely making long-term system operation impossible. Since long-term robot system operation is

a goal of the majority of robotics research, this is not yet a pressing ethical concern, but is one that is well recognized as important.

As one example of ethics applied to SAR in particular, Feil-Seifer and Mataric [73.176] outlines the ethical issues of SAR around the core principles of ethics applied to human subjects, namely beneficence, nonmaleficence, autonomy and justice. The first two principles encompass the SAR issues of relationships, authority and attachment, perception and personifications of the robot, and replacement of hu-

man care/changes to human-human interaction. The third principle, autonomy, spans the issues of privacy, choice, and intentional user deception. Finally, justice spans the complex issues of cost/benefit analysis, and locus of responsibility in the case of failure or harm.

As robots get closer to people, ethical issues become more pressing. It is a good sign that so early in the development of SAR those issues are being actively discussed and considered, toward the development of most ethically informed methods and systems.

74. Learning from Humans

Aude G. Billard, Sylvain Calinon, Rüdiger Dillmann

This chapter surveys the main approaches developed to date to endow robots with the ability to learn from human guidance. The field is best known as robot programming by demonstration, robot learning from/by demonstration, apprenticeship learning and imitation learning. We start with a brief historical overview of the field. We then summarize the various approaches taken to solve four main questions: when, what, who and when to imitate. We emphasize the importance of choosing well the interface and the channels used to convey the demonstrations, with an eye on interfaces providing force control and force feedback. We then review algorithmic approaches to model skills individually and as a compound and algorithms that combine learning from human guidance with reinforcement learning. We close with a look on the use of language to guide teaching and a list of open issues.

74.1 Learning of Robots

Robot learning from humans relates to situations in which the robot learns from interacting with a human. This must be contrasted to the vast body of work on robot learning where the robot learns *on its own*, that is, through trial and error and without external guidance. In this chapter, we cover works that combine reinforcement learning (RL) with techniques that use human guidance, e.g., to bootstrap the search in RL. However, we exclude from this survey all works that use purely reinforcement learning, even though one could argue that providing a reward is one form of human guidance. We consider that providing a reward function is akin to providing an objective function and hence refer the reader to the companion chapter on *Machine*

Learning for robotics. We also exclude works where the robot learns implicitly from being in presence of a human, while the human is not actively coaching the robot, as these works are covered in the companion chapter on *Social Robotics*. We hence focus our survey to all works where the human is actively teaching the robot, by providing *demonstrations* of how to perform the task.

Various terminologies have been used to refer to this body of work. These include programming by demonstration (PbD), learning from human demonstration (LfD), *imitation learning*, and *apprenticeship learning*. All of these refer to a general paradigm for enabling robots to autonomously perform new tasks from ob-

serving and learning, therefore, from the observation of humans performing these tasks.

74.1.1 Principle

Rather than requiring users to analytically decompose and manually program a desired behavior, work in **LfD-PbD** takes the view that an appropriate robot controller can be derived from observations of a human's own performance thereof. The aim is for robot capabilities to be more easily extended and adapted to novel situations, even by users without programming ability:

The main principle of robot learning from demonstration is that end-users can teach robots new tasks without programming.

Consider a household robot capable of performing manipulation tasks. One task that an end-user may desire the robot to perform is to prepare a meal, such as preparing an orange juice for breakfast (Fig. 74.1 and  VIDEO 29). Doing so may involve multiple sub-tasks, such as juicing the orange, throwing the rest of the orange in the trash, and pouring the liquid into a cup. Further, every time this meal is prepared, the robot will need to adapt its motion to the fact that the location and type object (cup, juicer) may change.

In a traditional programming scenario, a human programmer would have to code a robot controller that is capable of responding to any situation the robot may face. The overall task may need to be broken down into tens or hundreds of smaller steps, and each one of these steps should be tested for robustness prior to the robot leaving the factory. If and when failures occur in the field, highly-skilled technicians would need to be dispatched to update the system for the new circumstances. Instead, **LfD** allows the end-user to *program* the robot simply by showing it how to perform the task – no coding is required. Then, when failures occur, the end-user only needs to provide more demonstrations, rather than calling for professional help. **LfD** hence seeks to endow robots with the ability to learn what it means to perform a task by generalizing from several observations (Fig. 74.1 and  VIDEO 29).

LfD is not a record and play technique. **LfD** implies learning, henceforth, generalization.

Next, we give a brief historical overview of the way the field evolved over the years. This is followed, in Sect. 74.2, by an introduction to the issues at the core of **LfD**. In Sect. 74.3, we discuss the crucial role that the interface used for **LfD** plays in the success of the teaching, emphasizing how the choice of interface determines the type of information that can be conveyed to the robot. Finally, in Sect. 74.4, we give a generic

view of the main approaches to solving **LfD** and conclude with an outlook on open issues.

74.1.2 Brief History

Robot learning from demonstration started in the 1980s. Then, and still to a large extent now, robots had to be explicitly and tediously hand programmed for each task they had to perform. **PbD** sought to minimize, or even eliminate, this difficult step.

The rationale for moving from purely preprogrammed robots to very flexible user-based interfaces for training the robot to perform a task is threefold. First and foremost, **PbD** is a powerful mechanism for reducing the complexity of search spaces for learning. When observing either good or bad examples, one can reduce the search for a possible solution, by either starting the search from the observed good solution (local optima), or conversely, by eliminating from the search space what is known as a bad solution. Imitation learning is, thus, a powerful tool for enhancing and accelerating learning in both animals and artifacts.

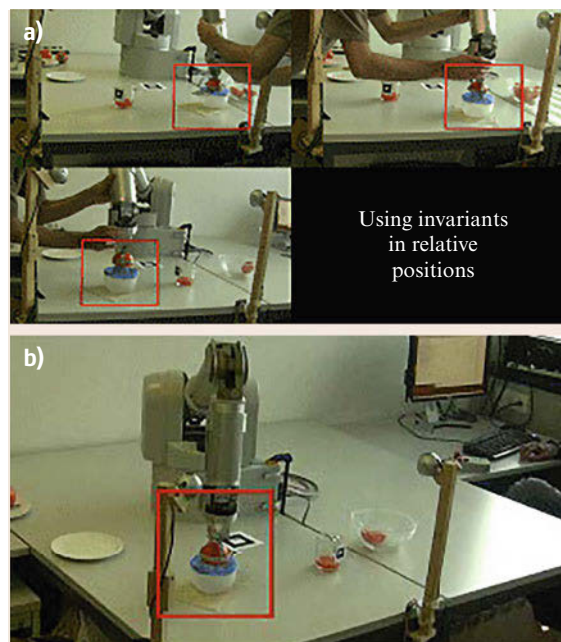

Fig. 74.1 (a) The teacher does several demonstrations of the task of juicing an orange, by changing the location of each item to allow the robot to generalize correctly. That is, the robot should be able to infer, by comparing the demonstrations, that only the relative locations matter, as opposed to the exact locations as recorded from a global coordinate system. (b) The robot can then reproduce the task even when the objects are located in positions not seen in the demonstrations  VIDEO 29

Second, imitation learning offers an implicit means of training a machine, such that explicit and tedious programming of a task by a human user can be minimized or eliminated. Imitation learning is thus a *natural* means of interacting with a machine that would be accessible to lay people.

Third, studying and modeling the coupling of perception and action, which is at the core of imitation learning, helps us to understand the mechanisms by which the self-organization of perception and action could arise during development. The reciprocal interaction of perception and action could explain how competence in motor control can be grounded in the rich structure of perceptual variables, and vice versa, how the processes of perception can develop as means to create successful actions.

PbD promises were thus multiple. On the one hand, one hoped that it would make the learning faster, in contrast to trial-and-error methods trying to learn the skill *tabula rasa*. On the other hand, one expected that being user-friendly, the methods would enhance the application of robots in human daily environments.

At the beginning of the 1980s, LfD, known then as programming by demonstration (PbD), started attracting attention in manufacturing robotics. PbD appeared as a promising route to automate the tedious manual programming of robots, reducing the costs involved in the development and maintenance of robots in the factory.

As a first approach in PbD, symbolic reasoning was commonly adopted in robotics [74.1–5], with processes referred to as *teach-in*, *guiding*, or *play-back* methods. In these works, PbD was performed through manual (teleoperated) control. The position of the end-effector and the forces applied on the object manipulated were stored throughout the demonstrations together with the positions and orientations of the obstacles and of the target. This sensorimotor information was then segmented into discrete subgoals (key points along the trajectory) and into appropriate pre-defined actions to attain these subgoals. Actions were commonly chosen to be simple point-to-point movements that industrial robots employed at this time. Examples of subgoals would be, e.g., the robot's gripper orientation and position in relation to the goal [74.3]. Consequently, the demonstrated task was segmented into a sequence of state-action-state transitions.

To take into account the variability of human motion and the noise inherent to the sensors capturing the movements, it appeared necessary to develop a method that would consolidate all demonstrated movements. For this purpose, the state-action-state sequence was converted into symbolic *if-then* rules, describing the

states and the actions according to symbolic relationships, such as *in contact*, *close-to*, *move-to*, *grasp-object*, *move-above*, etc. Appropriate numerical definitions of these symbols (i.e., when would an object be considered as *close-to* or *far-from*) were given as prior knowledge to the system. A complete demonstration was thus encoded in a graph-based representation, where each state constituted a graph node and each action a directed link between two nodes. Symbolic reasoning could then unify different graphical representations for the same task by merging and deleting nodes [74.2].

Munch et al. [74.6] suggested the use of machine learning (ML) techniques to recognize elementary operators (EOs), thus defining a discrete set of basic motor skills, with industrial robotics applications in mind. In this early work, the authors already established several key issues of PbD in robotics. These include questions such as how to generalize a task, how to reproduce a skill in a completely novel situation, how to evaluate a reproduction attempt, and how to better define the role of the user during learning. Munch et al. [74.6] admitted that generalizing over a sequence of discrete actions was only one part of the problem since the controller of the robot also required the learning of continuous trajectories to control the actuators. They proposed to overcome the missing parts of the learning process by leveraging them to the user, who took an active role in the teaching process.

These early works highlighted the importance of providing a set of examples that are usable by the robot: (1) by constraining the demonstrations to modalities that the robot can understand; and (2) by providing a sufficient number of examples to achieve a desired generality. They noted the importance of providing an adaptive controller to reproduce the task in new situations, that is, how to adjust an already acquired program. The evaluation of a reproduction attempt was also leveraged to the user by letting him/her provide additional examples of the skill in the regions of the learning space that had not been covered yet. In this way, the teacher/expert could control the generalization capabilities of the robot.

With the increasing development of mobile and humanoid robots, the field went on adopting an interdisciplinary approach, taking into account evidence of specific neural mechanisms for visuomotor imitation in primates [74.7–9] and of developmental stages of imitation capacities in children [74.10, 11]. The latter promotes the introduction of socially driven behavior in the robot to sustain interaction and improve teaching [74.12, 13] and of an interactive teaching process, in which the robot takes a more active role and may ask the user for additional sources of information, when

needed [74.14, 15]. Eventually, the notion of *robot programming by demonstration* was replaced by the more biological labeling of *imitation learning*. In essence, a large part of current works in PbD follow a conceptual approach very similar to that followed by these prior works.

Recent progress affected mostly the interfaces at the basis of the teaching. Traditional ways of guiding/teleoperating the robot have been progressively replaced by more user-friendly interfaces, such as vision [74.16, 17], speech command [74.18], data gloves [74.19], the laser range finder [74.20] or kinesthetic teaching (i.e., by manually guiding the robot's arms through the motion) [74.21–23].

The field progressively moved from simply copying the demonstrated movements to generalizing across sets of demonstrations. As machine learning progressed, PbD started incorporating more of those tools to tackle both the perception issue, i.e., how to generalize across

demonstrations, and the production issue, i.e., how to generalize the movement to new situations. Initially, tools such as artificial neural networks (ANNs) [74.24, 25], radial-basis function networks (RBFs) [74.26], and *fuzzy logic* [74.27] were quite popular. These have lately been replaced by hidden Markov models (HMMs) [74.28–33] and various non-linear regression techniques [74.21, 34, 35], as we will discuss in more detail in Sect. 74.4.

New learning challenges were, thus, set forth. Robots were expected to show a high degree of flexibility and versatility both in their learning system and in their control system in order to be able to interact naturally with human users and demonstrate similar skills (e.g., by moving in the same rooms and manipulating the same tools as humans). Robots were more and more expected to act *human-like* to enhance the interaction and so that their behavior would be more predictable and, hence, more acceptable.

74.2 Key Issues When Learning from Human Demonstrations

As mentioned in the beginning, learning from demonstration (LfD) has at core to develop algorithms that are generic in their representation of the skills and in the way they generate the skills.

The field has identified a number of key problems that need to be solved for ensuring such a generic approach to transferring skills across various agents and situations [74.36, 37]. These have been formulated as a set of generic questions, namely *what to imitate*, *how to imitate*, *when to imitate*, and *who to imitate*. These questions were formulated in response to the large body of diverse work in robotics LfD [74.18, 26, 38–41] that could not easily be unified under a small number of coherent operating principles. The above four questions and their solutions aim at being generic in the sense of making no assumptions on the type of skills that may be transmitted.

74.2.1 When and Whom to Imitate

Whom and when to imitate has been largely unexplored so far, and hence to date, only the first two questions have really been addressed. Figure 74.2 and  VIDEO 97 illustrate how these two problems can be solved in a principled manner through statistical observation of the demonstrations.

How to Determine the Evaluation Metric

What to imitate relates to the problem of determining which aspects of the demonstration should be imi-

tated. For a given task, certain observable or affectable properties may be irrelevant and safely ignored. For instance, if the demonstrator always approaches a location from the north, is it necessary for the robot to do the same? The answer to this question strongly in-

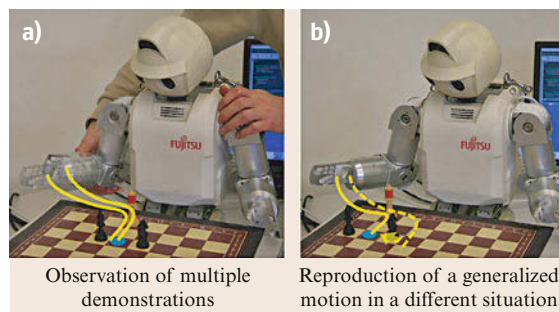

Fig. 74.2 (a) A robot learns how to make a chess move (namely moving the queen forward) by generalizing across different demonstrations of the task performed in slightly different situations (different starting positions of the hand). The robot records the trajectories of its joints and learns to extract invariant features (*what-to-imitate*), i.e., that the task constraints are reduced to a subpart of the motion located in a plane defined by the three chess pieces. (b) The robot reproduces the skill in a new context (for a different initial position of the chess piece) by finding an appropriate controller that satisfies both the task constraints and constraints relative to its body limitation (*how-to-imitate* problem) (after [74.21])

fluences whether or not a derived robot controller is a successful imitation – a robot that approaches from the south is appropriately trained if direction is not important, but needs further education if it is. This issue is related to questions of signal versus noise and is answered by determining the metric by which the resulting behavior is evaluated. Different ways can be taken to address this issue. The simplest approach is to take a statistical perspective and deem as relevant the parts (dimension, region of input space) of the data that are consistently measured across all demonstration instances [74.21]. If the dimension of the data is too high, such an approach may require too many demonstrations to gather enough statistics. An alternative is then to have the teacher help the robot determine what is relevant by pointing out the parts of the task that are most important.

In summary, what to imitate removes consideration of details that, while perceptible/performable, do not matter for the task. It participates in determining the metric by which the reproduction of the robot can be measured. In continuous control tasks, what to imitate relates to the problem of defining automatically the feature space for learning, as well the constraints and the cost function. In discrete control tasks, such as those treated by reinforcement learning and symbolic reasoning, what to imitate relates to the problem of how to define the state and action space and of how to automatically learn the pre/post conditions in an autonomous decision system.

74.2.2 How to Imitate and How to Solve the Correspondence Problem

How to imitate consists in determining how the robot will actually perform the learned behaviors to maximize the metric found when solving the what to imitate problem. Often, a robot cannot act exactly the same way as a human does, due to differences in physical embodiment. For example, if the demonstrator uses a foot to move an object, is it acceptable for a wheeled robot to bump it, or should it use a gripper instead? If the metric does not have appendage-specific terms, it may not matter.

This issue is closely related to that of the correspondence problem [74.36]. Robots and humans, while inhabiting the same space and interacting with the same objects, and perhaps even superficially similar, still perceive and interact with the world in fundamentally different ways. To evaluate the similarity between human behavior and that of robots, we must first deal with the fact that humans and robots may occupy different state spaces, of perhaps different dimensions. We identify two different ways in which states of demonstrator

and imitator can be said to correspond, and give brief examples:

- *Perceptual equivalence*: Due to differences between human and robot sensory capabilities, the same scene may appear to be very different. For instance, while a human may identify humans and

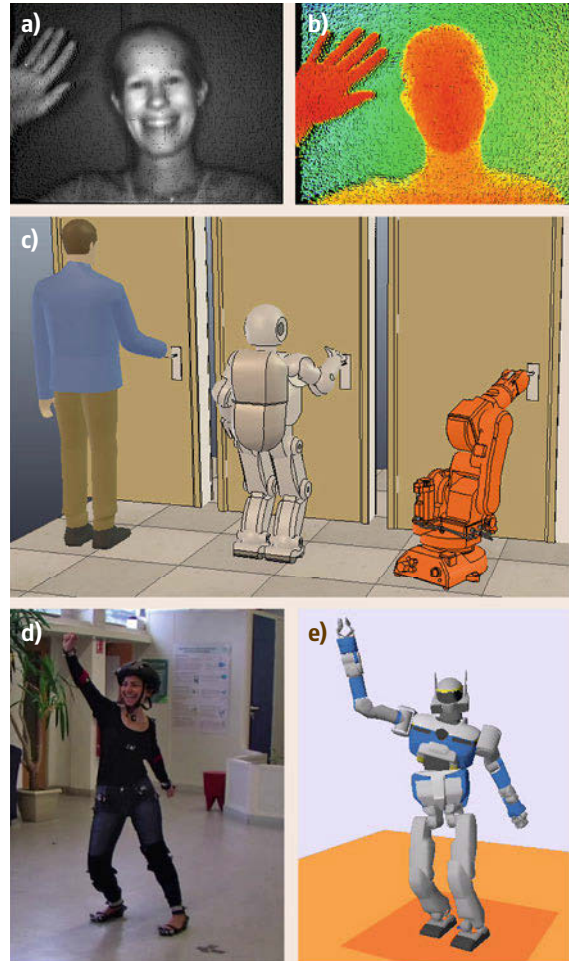

Fig. 74.3 (a,b) Perceptual equivalence (adapted from [74.42]). (c) Physical equivalence. The humanoid robot has the same arrangement of principal articulations as the human demonstrator, but different limb lengths and joint angle limits. The industrial robot has a different number and arrangement of articulations, which makes the mapping problem more challenging (illustration created with the V-REP simulator [74.43]). (d,e) Offline full-body motion transfer by taking into account the kinematic and dynamic disparity between the human and the humanoid [74.44]. See also [VIDEO 98](#) and [VIDEO 99](#) for example of mapping of full body motion from human to humanoids

gestures from color and intensity, a robot may use depth measurements to observe the same scene (Fig. 74.3a). Another point of comparison is tactile sensing. Most tactile sensors allow robots to perceive contact, but do not offer information about temperature, in contrast to the human skin. Moreover, the low resolution of the robots' tactile sensors does not allow robots to discriminate across the variety of existing textures, while human skin does. As the same data may, therefore, not be available to both humans and robots, successfully teaching a robot may require a good understanding of the robot's sensors and their limitations. *LfD* explores the limits of these perceptual equivalences, by building interfaces that either automatically correct or make explicit these differences.

- *Physical equivalence*: Due to differences between human and robot embodiments, humans and robots may perform different actions to accomplish the same physical effect. For instance, even when performing the same task (soccer), humans and robots may interact with the environment in different ways (Fig. 74.3b). Humans run and kick, while robots

roll and bump. Solving this discrepancy in motor capabilities is akin to solving the *how to imitate* problem to achieve the same effect. *LfD* develops way to solve this problem. Typically, the robot may compute a path (in Cartesian space) for its end-effector that is close to the path followed by the human hand, while relying on inverse kinematics to find the appropriate joint displacements. In the football example above, this would require the robot to determine a path for its center of mass which corresponds to the path followed by the human's right foot when projected on the ground. Clearly, this equivalence is very task dependent. Recent solutions to this problem for hand motion and body motion can be found in [74.45, 46].

We can think of perceptual equivalence as dealing with the manner in which the agents perceive the world. Perceptual equivalence requires to make sure that the information necessary to perform the task is available to both humans and robots. Physical equivalence deals with the manner in which agents affect and interact with the world, so that the task is performable by both agents.

74.3 Interfaces for Demonstration

The interface used to provide demonstration plays a key role in the way the information is gathered and transmitted. We distinguish three major trends:

1. One may directly record human motions. If one is interested solely in the kinematic of the motion, one may use any of the various existing motion tracking systems, whether these are based on vision, exoskeleton, or other types of wearable motion sensors. The left-hand side of Fig. 74.4b and  VIDEO 98 show an example of full body motion tracking during walking using vision. The motion of the human body is first extracted from the background using a model of human body. This model is subsequently mapped to an avatar and then to the humanoid robot DB at ATR, Kyoto, Japan. These external means of tracking human motion return precise measurement of the angular displacement of the limbs and joints. They have been used in various works for *LfD* of full body motion [74.33, 47–49]. These methods are advantageous in that they allow the human to move freely. However, they require solutions to the correspondence problem, i.e., the problem of how to transfer motion from human to robot when both differ in the kinematic and

dynamics of their body or, in other words, if the configuration space is of different dimension and size. This is typically done when mapping the motion of the joints that are tracked visually to a model of the human body that matches closely that of the robot. Such mapping would be particularly difficult to perform when the walking machine (e.g., a hexapod) differs importantly from the human body. The problem of mapping actions across two dissimilar bodies was already evoked earlier on and refers to the correspondence problem.

2. Second, there are techniques such as kinesthetic teaching, where the robot is physically guided through the task by the human. This approach simplifies the correspondence problem by letting the user demonstrate the skill in the robot's environment with the robot's own capabilities. It also provides a natural teaching interface to correct a skill reproduced by the robot. Recent advances in skin technology offer the possibility to teach robots how to exploit tactile contact on an object (Fig. 74.4 middle and  VIDEO 104). By exploiting the compliance of the iCub robot's fingers, the teacher can teach the robot how to adapt the posture of the fingers in response to a change in tactile sensing as measured at the robot's finger tips [74.50]).

One main drawback of kinesthetic teaching is that the human must often use more degrees of freedom to move the robot than the number of degrees of freedom moved on the robot. This is visible in Fig. 74.4. To move the fingers of one hand of the robot, the teacher must use both hands. This limits the type of tasks that can be taught through kinesthetic teaching. Typically tasks that would require moving both hands simultaneously could not be taught this way. One could either proceed incrementally, teaching first the task for the right hand and then, while the robot replays the motion with its right hand, teach the motion of the left hand. However, this may prove to be cumbersome. The use of external trackers as reviewed above are more amenable to teaching coordinated motion between several limbs.

3. Third, there are immersive teleoperation scenarios, where a human operator is limited to using the robot's own sensors and effectors to perform the task. Teleoperation may be done using simple joysticks or other remote control devices, including haptic devices (Fig. 74.4 bottom and [VIDEO 101](#)). The latter have the advantage that they can allow the teacher to teach tasks that require precise control of forces, while joysticks would only provide kinematic information (position, speed).

Teleoperation is advantageous compared to external motion tracking systems, as this solves the correspondence problem entirely, since the system directly records the perception and action from the robot's configuration space. It is also advantageous compared to kinesthetic training, as it allows training the robots from a distance and is, hence, particularly suited for teaching navigation and locomotion patterns. The teacher no longer needs to share the same space with the robot. Teleoperation is, usually, used to transmit the kinematics of motion. For instance, in [74.51], the acrobatic trajectories of a helicopter are learned by recording the motion of the helicopter when teleoperated by an expert pilot. In [74.52], a robot dog is taught to play soccer by a human guiding it via a joystick. However, in recent work, teleoperation has been used successfully to teach a humanoid robot balancing techniques [74.53]. Learning to react to perturbations is done through a haptic interface attached to the torso of the demonstrator, which measures the interaction forces when the human is pushed around. The kinematics of motion of the demonstrator are directly transmitted to the robot through teleoperation and are combined with haptic information to train a model of motion conditioned on perceived forces.

The disadvantage of teleoperation techniques is that the teacher often needs training to learn to use the remote control device. Teleoperation using a simple joystick allows guiding only a subset of degrees of freedom. To control for all degrees of freedom, very complex, exoskeleton type of devices must be used, which can be cumbersome. Moreover, teleoperation prevents the teacher from observing all sensorial information required to perform the task. For instance, teleoperation, even when using haptic device, poorly renders the contacts perceived at the robot's end-effector. To palliate to this, one may provide the teacher with visualization interfaces to simulate the interaction forces.

4. Lastly, one can use explicit information, such as that conveyed by speech, to provide additional advice and comments to the demonstration [74.18, 57, 58] and [VIDEO 103](#). Speech is a very natural means of communication among humans and, hence, is viewed as an easy way to allow the end-user to communicate with robots. However, it necessitates that vocabulary that is understandable to the robot and

Fig. 74.4 (a) Demonstration by visual tracking of gestures (after [74.54], [VIDEO 98](#) and [VIDEO 99](#)). (b) Demonstration by kinesthetic teaching (after [74.55] and [VIDEO 104](#)). (c) Demonstration by teleoperation (after [74.56] and [VIDEO 101](#))

grounded in the actions and perceptions of the robot be defined beforehand. While this restricts teaching to discrete state–action pairs, it is particularly useful for symbolic reasoning.

Each teaching interface has its pros and cons. It is thus interesting to investigate how these interfaces could be used in conjunction to exploit complementary information provided by each modality [74.50].

74.4 Algorithms to Learn from Humans

Current approaches to encoding skills through **LfD** can be broadly divided into two trends: a low-level representation of the skill, taking the form of a non-linear mapping between sensory and motor information, and, a high-level representation of the skill that decomposes the skill into a sequence of action-perception units.

While the majority of work in **LfD** uses solely the demonstrations for learning, a growing number of works develops methods by which **LfD** can be combined with other learning techniques. One group of work investigates how to combine imitation learning with *reinforcement learning*, a method by which the robot learns through trial and error to maximize a given reward. Other works take inspiration in the way humans teach each other and introduce interactive and bidirectional teaching scenarios whereby the robot becomes an active partner during the teaching phase. We briefly review the main principles underlying each of these areas below:

74.4.1 Learning Individual Motions

Individual motions/actions (e.g., juicing an orange, trashing it, and pouring liquid into the cup in the example shown in 74.1) could be taught separately instead of simultaneously, as shown in this previous example. The human teacher would then provide one or more examples of each submotion. If learning proceeds from the

observation of a single instance of the motion/action, one calls this *one-shot* learning [74.60]. Examples of learning locomotion patterns can be found in [74.61]. To make sure that this is not akin to simple record and play, the controller is provided with prior knowledge in the form of primitive motion patterns. Learning then consists of instantiating the parameters modulating these motion patterns.

Teaching can also proceed in batch mode after recording several demonstrations, or incrementally by adding recursively more information trial by trial [74.12, 50, 62]. When learning in batch mode, learning considers all examples and draws inference by comparing the individual demonstrations. Inference is usually based on a statistical analysis, where the demonstration signals are modeled via a probability density function, exploiting various non-linear regression techniques stemming from machine learning. Popular methods these days include Gaussian processes, Gaussian mixture Models, and support vector machines.

Choosing properly the variables to encode a particular movement is crucial, as it already implies part of the solution to the problem of defining what is important to imitate. Work in **LfD** encodes human movements in either joint space, task space, or torque space [74.63–65]. The encoding may be specific to cyclic motion [74.22], discrete motion [74.21], or to a combination of both [74.61].

Fig. 74.5 Probabilistic encoding of motion in a subspace of reduced dimensionality (after [74.59] and VIDEO 102)

Encoding often encompasses the use of dimensionality reduction techniques that project the recorded signals into a latent space of motion of reduced dimensionality. These techniques may either perform a local linear transformations [74.66–68] or exploit global non-linear methods [74.59, 69, 70] (Fig. 74.5). Additionally, task-specific rating functions [74.71] and simulation-based optimization [74.72] are investigated to identify relevant learning features.

Teaching Force–Control Tasks

While most **LfD** to date work focused on learning the kinematics of motions by recording the position of the end-effector and/or the position of the robot's joints, more recently, some works have investigated transmission of force-based signals through human demonstration [74.56, 73–76]. See  VIDEO 478 and  VIDEO 479 for examples of kinesthetic teaching of compliant motion. Transmitting information about force is difficult for humans and for robots alike. Force can be sensed only when performing the task ourselves. Current efforts, hence, seek to develop methods by which one may *embody* the robot. This allows human and robot to simultaneously perceive the forces applied when performing the task. A new exciting line of research, hence, leverages on recent advances in the design of haptic devices and tactile sensing, and on the development of torque and variable impedance actuated systems to teach force-control tasks through human demonstration.

74.4.2 Learning Compound Actions

Learning complex tasks, composed of a combination and juxtaposition of individual motions, is the ultimate goal of **LfD**. There are two major ways to proceed to learning of such complex tasks:

1. One may first learn models of all individual motions, using demonstrations of each of these actions individually. In a second stage, one may learn the right sequence and combination of these actions by observing a human performing the whole task. This approach, however, assumes that one can list all necessary individual actions, so-called *primitive* actions. To date, there does not exist a database of such primitive actions and one may wonder whether the variability of human motion may really be reduced to a finite list of possible motions. A common approach is to first learn models of all of the individual motions, using demonstrations of each of these actions individually [74.77, 78], and then learn the right sequencing/combination in a second stage either by observing a human performing the whole task [74.79, 80] or through reinforcement learning [74.81]. However, this approach assumes that there is a known set of all necessary primitive actions. For specific tasks this may be true, but to date there does not exist a database of general purpose primitive actions, and it is unclear whether the variability of human motion may really be reduced to a finite list.
2. The alternative is to observe the human performing the complete task and to automatically segment the task to extract the primitive actions, which may then become task-dependent, see e.g., [74.82, 83]. This has the advantage of learning, in one swipe, both the primitive actions and the way they should be combined. One issue that arises is that the number of primitive tasks is often unknown, and there could be multiple possible segmentations that must be considered [74.52].

Other examples include learning how to sequence known behaviors to enable complex navigation tasks through the imitation of a more knowledgeable robots or humans [74.9, 84, 85] and learning how to sequence primitive motions for full body motion in humanoid robots [74.25, 33, 86].

A large body of these works uses a symbolic representation of both the learning and the encoding of the task [74.6, 30, 85, 87–91]. This symbolic way of encoding skills may take several forms. One common way is to segment and encode the task according to sequences of *predefined* actions, described symbolically. Encoding and regenerating the sequences of these actions can, however, be done using classical machine learning techniques, such as **HMM**, [74.30].

Often, these actions are encoded in a hierarchical manner. In [74.85], a graph-based approach is used to generalize an object moving skill, using a wheeled mobile robot. In this model, each node in the graph represents a complete behavior and generalization takes place at the level of the topological representation of the graph. The latter is updated incrementally.

References [74.88, 89] follow a similar hierarchical and incremental approach to encode various household tasks (such as setting the table and putting dishes in a dishwasher) (Fig. 74.6 and  VIDEO 103). There, learning consists in identifying a sequence of predefined, elementary actions, which is further combined into a hierarchical task network. By analyzing multiple demonstrations, the ordering of elementary actions is learned, resulting in a precedence graph. The precedence graph defines a partial ordering on the set of learned elementary actions, which can be exploited to execute elementary actions in parallel, extracting symbolic rules that manage the way each object must be

handled. In [74.92], the approach was extended to learning subsymbolic goal and constraint descriptions for each elementary action. In the execution phase, the robot applies motion planning to generate a motion to reach the goals while obeying the constraints. The resulting task description mimics the strategy that humans follow when performing the task. Based on the subsymbolic goal and constraint descriptions, the robot can reason to adapt the strategy to changes in object location, obstacle occurrence, and varying start configurations.

The approaches reviewed above assume a deterministic world, where actions unfold uniquely from perception of the current state of the world. However, robots operating in real environments will observe the world using imperfect sensors and the effects of their actions may be stochastic. To account for the stochasticity of the robot's perceptions and actions, *Schmidt-Rohr et al.* [74.93] use a model of the task with partially observable Markov decision processes (POMDP). At run time, an optimal (in a maximum likelihood sense) decision is then taken.

Reference [74.90] exploits also a hierarchical approach to encoding a skill in terms of pre-defined behaviors. The skill consists in moving through a maze where a wheeled robot must avoid several kinds of obstacles and reach a set of specific subgoals. The particularity of this approach lies in the use of symbolic representations of the skill, which are applied to explore the role of the teacher in guiding incremental learning of the robot.

Finally, [74.91] took a symbolic approach to encoding human motions as sets of pre-defined postures, positions, or configurations, considering different levels of granularity for the symbolic representation of the motion. This a priori knowledge is then used to explore the correspondence problem through several simulated setups, including motion in joint space of arm links and displacements of objects on a two-dimensional (2-D) plane.

The main advantage of these symbolic approaches is that high-level skills (consisting of sequences of symbolic cues) can be learned efficiently through an interactive process. However, because of the symbolic nature of their encoding, the methods rely on a large amount of prior knowledge to predefine the important cues and to segment those efficiently.

74.4.3 Incremental Teaching Methods

The statistical approach described previously is an interesting way to extract autonomously the important features of the task, and, thus to avoid putting too much prior knowledge in the system. However, it requires a large number of demonstrations to draw statistically valid inference. It is not reasonable to assume that a layuser will perform many demonstrations of the same task. Hence, for LfD to be amenable to lay users, learning should require as few demonstrations as possible. Ideally, one would like the robot to be bootstrapped with some initial knowledge, so that the robot can start

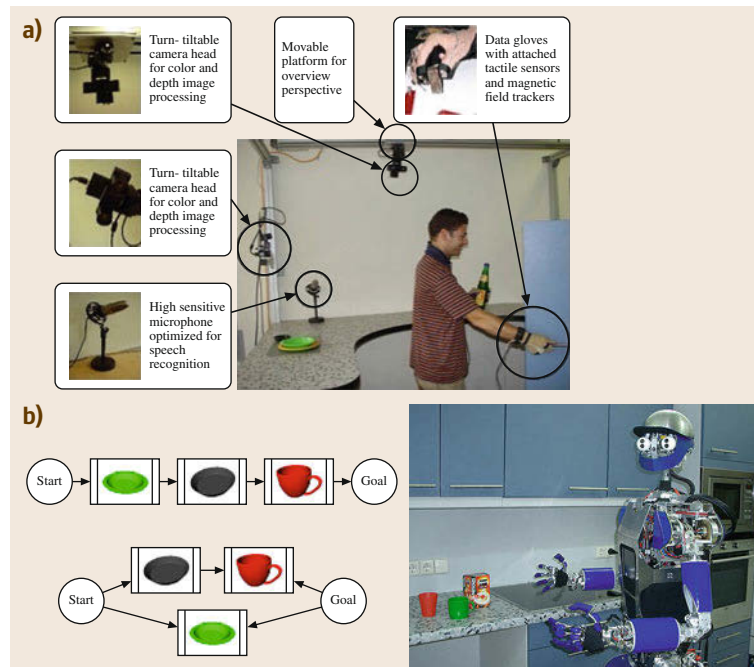

Fig. 74.6 (a) Training center with dedicated sensors. (b) Precedence graphs learned by the system for the *setting the table* task. (c) Initial task precedence graph for the first three demonstrations. (d) Final task precedence graph after observing additional examples (after [74.88]) (VIDEO 103)

right away to perform the task, and human training would be used solely to help the robot gradually improve its performance.

Incremental learning approaches that gradually refine task knowledge as more examples become available pave the way towards **LfD** systems suitable for such continuous and long-life robot learning. Figure 74.7 and [VIDEO 104](#) shows an example of such incremental teaching of a simple skill.

These incremental learning methods use various forms of deixis, as well as verbal and non-verbal interactions, to guide the robot's attention to the important parts of the demonstration or to particular mistakes produced by the robot during the reproduction of the task. Such incremental and guided learning is often referred to as *scaffolding* or *molding* of the robot's knowledge, and is key to teaching robots tasks of increasing complexity [74.90, 94].

Research on the use of incremental learning techniques for robot **LfD** has contributed to the development of methods for learning complex tasks within the household domain from as few demonstrations as possible. Moreover, it has contributed to the development and application of machine learning that allow a continuous and incremental refinement of the task model. Such systems have sometimes been referred to as *background knowledge-based* or *EM deductive LfD-systems*, as presented in [74.95, 96]. They usually require very few or even only a single user demonstration to generate executable task descriptions. The main objective of this line of research is to build a meta-representation of the knowledge that the robot has acquired on the task and to apply reasoning methods on this knowledge database (Fig. 74.6). In this scenario, reasoning involves recognizing, learning, and representing repetitive tasks.

Pardowitz et al. [74.97] discuss how different forms of knowledge can be balanced in an incremental learning system. The system relies on building *task precedence graphs*. Task precedence graphs encode hypotheses that the system makes on the sequential structure of a task. Learning of the task precedence graphs allows the system to schedule its operations most flexibly,

while still meeting the goals of the task ([74.98] for details). Task precedence graphs are directed, acyclic graphs that contain a temporal precedence relation that can be learned incrementally. Incremental learning of task precedence graphs leads to a more general and flexible representation of the task knowledge (Fig. 74.6 and [VIDEO 105](#)).

74.4.4 Combining Learning from Humans with Other Learning Techniques

To recall, a main argument for the development of **LfD** methods was that they would speed up learning by providing examples of *good solutions*. This assumption, however, is realistic only if the context for the reproduction is sufficiently similar to that of the demonstration. We saw previously that the use of dynamical systems-based representation at the trajectory level allows the robot to depart to some extent from a learned trajectory to reach the target, even when both the object and the hand of the robot have moved from the location shown during the demonstration. There are, however, situations in which such an approach would fail, such as, for instance, when placing a large obstacle in the robot's pathway (Fig. 74.8). Besides, robots and humans may differ significantly in their kinematics and dynamics of motion and, although there are varieties of ways to bypass the so-called correspondence problem, relearning a new model may still be required in special cases.

To allow the robot to relearn to perform a task in any new situation, it appeared important to combine **LfD** methods with other motor learning techniques. Reinforcement learning (**RL**) appeared particularly suitable for type of problem. Indeed, imitation learning is limiting in that it requires the robot to learn only from what has been demonstrated. Reinforcement learning, in contrast, allows the robot to discover new control policies through free exploration of the state-action space. Approaches that combine imitation learning and reinforcement learning aim at exploiting the strength of both algorithms to overcome their respective drawbacks. Demonstrations are used to guide the exploration

Fig. 74.7 An incremental learning strategy where a manipulation skill is first demonstrated through the use of a data glove. After a first reproduction trial, the skill is refined through kinesthetic teaching, by exploiting the tactile capabilities of the iCub humanoid robot (after [74.50]) ([VIDEO 104](#))

in reinforcement learning (RL). This, hence, reduces the time it takes for RL algorithms to find an adequate control policy, while allowing the robot to depart from the demonstrated behavior. Figures 74.8 show two examples of techniques that use reinforcement learning in conjunction with LfD to improve the robot's performance beyond that of a demonstrator.

Early work on LfD using RL started in the 1990s with learning to swing up and control an inverse pendulum [74.100] and learning industrial tasks like peg-in-hole with a robot arm [74.26]. More recent efforts include [74.101–103], who tackled robust control of the upper body of humanoid robots in various manipulation tasks, learning an archery skill [74.104], and learning how to hit a snooker ball [74.105].

Demonstrations can be used in different ways to bootstrap RL. They may be used as initial roll-outs from which an initial estimate of the policy is computed [74.106–108], or to generate an initial set of primitives [74.81, 103, 107]. In the latter case, RL is then used to learn how to select across these primitives. Demonstrations can also be used to limit the search space covered by RL [74.101, 109], or to estimate the reward function [74.110, 111]. Finally, RL and imitation learning can be used in conjunction at run time, by letting the demonstrator take over part of the control during one trial [74.112].

Another way to enable the robot to learn a control strategy through a combination of self-experimentation and learning from watching others is to evolve population of agents that mimic each other. Such an evolutionary approach using genetic algorithms has been investigated by a number of authors, e.g., for learning of manipulation skills [74.113], navigation strategies [74.114], or sharing a common vocabulary to name sensoriperception and actions [74.115].

Variants on Reinforcement Learning

While most of the works that combine imitation learning with reinforcement learning assume the reward to be known, inverse reinforcement learning (IRL) offers a framework to determine automatically the reward and the optimal control policy [74.116]. When using human demonstrations to guide learning, IRL solves jointly

the *what to imitate* and *how to imitate* problems. Other approaches to estimating the reward or cost function automatically have been proposed, see, for instance, the maximum margin planning technique [74.117] and the automatic extraction of constraints [74.118].

Underlying all IRL works is the assumption of a consistent reward function. When demonstrations are provided by multiple experts, this assumes that all experts optimize the same objectives. This is constraining and does not exploit the variability of ways in which humans may solve the same task. Recent IRL works consider multiple experts and identify multiple different reward functions [74.119, 120]. This allows the robots to learn multiple (albeit suboptimal) ways to perform the same task. The hope is that this multiplicity of policies will make the controller more robust, offering alternative ways to complete the task, when the context no longer allows the robot to perform the task in the optimal way.

The vast majority of work on LfD relies on successful demonstrations of the desired task by the human. It hence assumes that all the demonstrations are good demonstrations and discards those that are poor proxy of what would be deemed as a good demonstration. Recent work has also investigated the possibility that demonstrations may instead be failed attempts at performing the task [74.121, 122]. Learning then proceeds from observing solely incorrect demonstrations (VIDEO 476 and VIDEO 477). Note that demonstrations are never completely incorrect. Learning from failed demonstration then attempts to discover which parts of the demonstrations were correct and which were incorrect, so as to improve solely the incorrect parts. In this context, LfD addresses the questions of *what to* and *what not to* imitate. It offers an interesting alternative to approaches that combine imitation learning and reinforcement learning, in that no reward needs to be explicitly determined.

74.4.5 Learning from Humans, a Form of Human–Robot Interaction

Another perspective adopted by LfD to make the transfer of skill more efficient is to focus on the interaction

Fig. 74.8 Illustration of the use of reinforcement learning in policy parameter space to refine a skill initially learned from demonstration (after [74.99] and VIDEO 105)

aspect of the transfer process. As this transfer problem is complex and involves a combination of social mechanisms, several insights from human–robot interaction (HRI) were explored to make efficient use of the teaching capabilities of the human user, [74.123–125] for surveys. Next, we briefly survey some of these works.

The development of algorithms for detecting *social cues* given implicitly or explicitly by the teacher during training and the integration of those as part of other generic mechanisms for LfD has become the focus of a large body of work in LfD. Such social cues can be viewed as a way to introduce priors in a statistical learning system, and, by so doing, to speed up learning. Indeed, several hints can be used to transfer a skill not only by demonstrating the task multiple times but also by highlighting the important components of the skill. This can be achieved by various means, using different modalities.

A large body of work explored the use of pointing and gazing (Fig. 74.9 left and  VIDEO 106) as a way of conveying the intention of the user [74.79, 126–132]. Vocal deixis, using a standard speech recognition engine, has also been explored widely [74.79, 133]. In [74.88], the user makes vocal comments to highlight the steps of the teaching that are deemed as being the most important. In [74.134, 135], only the prosody of the speech pattern is looked at, rather than the exact content of the speech, as a way to infer some information on the user's communicative intent.

In [74.136], these social cues are learned through an imitative game, whereby the user imitates the robot. This allows the robot to build a user-specific model of these social pointers, and, hence be more robust to detecting those.

Recent lines of research in interactive LfD seeks to give a more active role to the teacher in a bidirectional teaching process [74.15, 137, 138]. Robots become more active partners and can indicate which portion of the demonstration was unclear. Teachers may in turn refine the robot's knowledge by providing complementary information where the robot is performing poorly. This supplementary information may consist of additional rounds of demonstrations of the complete task [74.139], or may be limited to subparts of the task [74.140, 141]. The information can be conveyed through specific task's features, such as a list of way-points [74.142]. The robot is then left free to interpolate a trajectory using these key points.

The design of such incremental teaching methods calls for machine learning techniques that enable the incorporation of new data in a robust manner. It also opens the door to the design of other human–robot interfacing systems, including the use of speech, which leads to meaningful dialogs between humans and robots. An example of such bidirectional teaching is given on the right-hand side of Fig. 74.10. The robot asks for help during or after teaching, verifying that its understanding of the task is correct [74.14]. This teaching interaction is tailored to let the user become an active participant in the learning process (and not only a model of expert behavior).

By taking inspiration from the human tutelage paradigm, [74.15] shows that a socially guided approach can improve both the human–robot interaction and the machine learning process by taking into account *human benevolence*. That work highlights the role of the teacher in organizing the skill into manageable steps and maintaining an accurate mental model

Fig. 74.9 Illustration of the use of social cues to speed up the imitation learning process. Here, gazing and pointing information are used to select probabilistically the objects relevant for the manipulation skill ( VIDEO 106)

Fig. 74.10 Example of an active teaching scenario. The robot asks for help during or after teaching, verifying that its understanding of the task is correct (after [74.14]) ( VIDEO 107)

of the learner's understanding. Reference [74.138] use a similar teaching paradigm and extend the concept to the learning of continuous motion trajectories and of actions on objects, and propose experiments where a humanoid robot learns new manipulation skills by first observing a human demonstrator (through motion sensors) and then gradually refining its skill through teacher support. In this application, the user provides scaffolds to the robot for the reproduction of the skill by moving kinesthetically a subset of the motors. Through the supervision of the user who progressively dismantles the scaffolds after each reproduction attempt, the robot can finally reproduce the skill on its own. Reference [74.143] highlights the importance of an active participation of the teacher not only to demonstrate a model of expert behavior but also to refine the acquired motion through spoken feedback.

Reference [74.90] provides experiments where a wheeled robot is teleoperated through a screen interface to simulate a *molding* process, that is, by letting the robot experience sensory information when exploring its environment through the teacher's support. Their model uses a memory-based approach in which the user provides labels for the different components of the task to teach hierarchically high-level behaviors.

Finally, a core idea of the HRI approach to LfD is that imitation is goal directed, that is, actions are meant to fulfill a specific purpose and to convey the intention of the actor [74.144]. While a longstanding trend in LfD approached the problem from the standpoint of

trajectory following [74.84, 145, 146] and joint motion replication, [74.147–150], recent works, inspired by the above rationale, start from the assumption that imitation is not just about observing and replicating the motion, but rather about *understanding* the goals of a given action (see the above survey of approaches to determining automatically the reward or what to imitate).

Determining the way humans learn to both extract the goals of a set of observed actions and give these goals a hierarchy of preference is fundamental to our understanding of the underlying decisional process to imitation. While we have surveyed recent work in that area, it is important to recall other approaches to tackling these issues that have previously followed a probabilistic approach to explain the derivation and sequential application of goals and apply this to enable learning of manipulatory tasks requiring sequencing of subsets of goals [74.97, 145, 151, 152].

Understanding the goal of the task is still only half of the picture, as there may be several ways of achieving the goal of the task. Moreover, what is feasible (or optimal) for the demonstrator may not necessarily be appropriate for the imitator [74.36]. Thus, different models, modes and communication channels, should be used in conjunction to find a solution that is optimal both from the point of view of the imitator and that achieves what the demonstrator seeks to teach the robot.

This concludes our survey. As the reader can see, the issues of what and how to imitate are tightly connected and to a large extent remain only partly solved.

74.5 Conclusions and Open Issues in Robot LfD

Research in LfD or programming by demonstration (PbD) is progressing rapidly, pushing back limits and posing new questions all the time. As such, any list of limitations and open questions is bound to be incomplete and out of date. However, there are a few long-standing limitations and open questions that bear further attention.

Generally, work in LfD assumes a fixed, given form for the robot's control policy, and learns appropriate parameters. To date, there are several different forms of policies in common usage, and there is no clear correct (or dominant) technique. Furthermore, it is possible that a system could be provided with multiple possible representations of controllers and select which is most appropriate.

The combination of reinforcement learning and imitation learning has been shown to be effective in addressing the acquisition of skills that require fine tuning of the robot's dynamics. Likewise, more interactive

learning techniques have proven successful in allowing for collaborative improvement of the learnt policy by switching between human-guided and robot-initiated learning. However, there do not yet exist protocols to determine when it is best to switch between the various learning modes available. The answer may, in fact, be task dependent.

In work to date, teaching is usually done by a single teacher, or teachers with an explicit concept of the task to teach. More work needs to be done to address issues related to conflicting demonstrations across teachers with different styles. Similarly, teachers are usually human beings, but could instead be an arbitrary expert agent. This agent could be a more knowledgeable robot or a computer simulation. Finally, another relatively little explored question relates to the problem of how to transfer skills across multiple agents, including multiple robots (i. e., teaching is done from a teacher robot to various learner robots). Early work in this direction was

done in the 1990s [74.115, 153, 154]. This work, however, has so far been reduced to transfer of navigation or communication skills across swarms of simple mobile robots.

Experiments in LfD have mostly focused on a single task (or set of closely related tasks), and each experiment starts with a tabula rasa. As learning of

complex tasks progresses, means to store and reuse prior knowledge at a large scale will have to be devised. Learning stages, akin perhaps to those found in child development, may be required. There will need to be a formalism to allow the robot to select information, to reduce redundant information, select features, and store new data efficiently.

75. Biologically Inspired Robotics

Fumiya Iida, Auke Jan Ijspeert

Throughout the history of robotics research, nature has been providing numerous ideas and inspirations to robotics engineers. Small insect-like robots, for example, usually make use of reflexive behaviors to avoid obstacles during locomotion, whereas large bipedal robots are designed to control complex human-like leg for climbing up and down stairs. While providing an overview of bio-inspired robotics, this chapter particularly focus on research which aims to employ robotics systems and technologies for our deeper understanding of biological systems. Unlike most of the other robotics research where researchers attempt to develop robotic applications, these types of bio-inspired robots are generally developed to test unsolved hypotheses in biological sciences. Through close collaborations between biologists and roboticists, bio-inspired robotics research contributes not only to elucidating challenging questions in nature but also to developing novel technologies for robotics applications. In this chapter, we first provide a brief historical background of this research area and then an overview of ongoing research methodologies. A few representative case studies will detail the successful instances in which robotics technologies help identifying biological hypotheses. And finally we discuss challenges and perspectives in the field.

Biologically inspired robotics (or bio-inspired robotics in short) is a very broad research area because almost all robotic systems are, in one way or the other, inspired from biological systems. Therefore, there is no clear distinction between bio-inspired robots and the others, and there is no commonly agreed definition [75.1]. For example, legged robots that walk, hop, and run are usually regarded as bio-inspired robots because many

biological systems rely on legged locomotion for their survival. On the other hand, many robotics researchers implement biological models of motion control and navigation onto wheeled platforms, which could also be regarded as bio-inspired robots [75.2].

75.1 General Background

The broad spectrum of bio-inspired robotics research is reflected to a variety of synonyms used in different scientific communities. For example, biomimetics and bionics are usually used to represent the types of research in which researchers observe biological systems and extract design principles for robotic applications. The terms bio-robotics and bio-engineering are also used interchangeably to biomimetics and bionics, but they often refer to engineered solutions specifically for biomedical applications. Another approach, usually classified as artificial life, biological cybernetics, or biophysics, investigates biological systems by using synthetic approaches. Here biological systems are typically viewed as mechanical and chemical entities and characterized by mechanistic models that are often very similar to the bio-inspired robots. The definitions and types of research studies conducted in these research areas are often overlapping, and many research projects provide results across the different areas.

While some of these research areas are also covered in the other chapters of this handbook, one of the most prominent, and more importantly useful, aspects of bio-inspired robotics lies in the contributions of robotics research for biological sciences. In contrast to the other robotics research, a significant number of bio-inspired robots were developed for the purpose of testing hypotheses concerning biological systems and for identifying the underlying mechanisms of biological systems that are very difficult to be clarified otherwise. In this chapter, we specifically focus on this aspect of bio-inspired robotics.

75.1.1 Brief History and Conceptual Background

There is a long history of the engineers' desire to replicating biological systems into artificial ones, including the famous examples of Japanese Karakuri dolls and Swiss automata several centuries ago (Fig. 75.1). Similarly, scientific efforts to use robotic systems to understand biological systems have also a relatively long history, which goes back even before the modern robotics started. One of the most influential examples in the earlier ages can be represented by the works in the field of cybernetics in which a number of system theories such as the concepts of feedback and feedforward were applied to understand phenomena in biological systems [75.3, 4].

The rise of neuroscience in the mid-twentieth century influenced bio-inspired robotics research significantly. In the 1950s, one of the first bio-inspired robots, Tortoises, was built by Grey Walter, a neurophysi-

ologist. The work was mainly driven by biological questions, such as how a simple neuron connectivity can result in richness of sensory-motor behaviors, and a turtle-like robot consisting of analog electronics, sensors, and electric motors demonstrated reflexive behaviors as well as basic motor learning in autonomous robots [75.5]. Another physiologist, *Valentino Braitenberg*, also explored the power of *understanding by building* approach, which led to the famous thought experiments of Braitenberg Vehicles, i.e., a series of imaginary mobile robots that are still often used to teach the relationship between neural connectivity and sensory-motor behaviors [75.6].

The invention of digital computers was also another historical milestone in bio-inspired robotics. The pioneers of digital computers such as *John von Neumann* and *Alan Turing* provided significant influences in the biological studies through their seminal works on self-replication and self-organization [75.7, 8], and the subsequent foundation of the field of Artificial Intelligence in the 1950s was driven based on the understanding of human intelligence especially from the computational standpoint [75.9].

While the power of digital computers dominated bio-inspired robotics for a while, the study of insect-like reflexive behaviors became popular again in the 1980s with the emergence of behavior-based robotics. The intensive studies of this approach shed light on the massively parallel nature of motion control processes, and demonstrated behaviors that cannot be fully explained by the conventional *sense-think-act* style control approach [75.10, 11]. One of the main contributions of this line of studies lies in the fact that the diversity and flexibility of control architecture is essential in adaptive behaviors in real-world systems, and the complexity of behaviors is not necessarily originated in the complexity of controller but in physical system–environment interactions [75.12].

Since then the research on physical system–environment interactions has been very popular in the interdisciplinary community of embodied cognitive science and artificial intelligence in which roboticists, biologists, computer scientists, and physicists work together to look into further details of underlying mechanisms of adaptivity in biological systems. Here the body as a physical entity is not only considered as a necessary *container* of intelligent adaptive behaviors but it also plays a central role that induces self-organization of patterns and structures in adaptive intelligent behaviors [75.13–15]. In this context, robotics methodologies and technologies are used to investigate hypotheses about the roles of embodiment that cannot be easily tested in animals.

Fig.75.1a–e Examples of bio-inspired robots in the history. (a) Japanese Karakuri doll, (b) Swiss Automaton, (c) Grey Walter's Tortoises Robot (after [75.5]), (d) Braitenberg Vehicle (after [75.6]), and (e) a cleaning robot Roomba as an example of behavior-based robotics application

75.2 Methodology

In order to provide contributions to both robotics and biological sciences, bio-inspired robotics research usually follows a series of unique research processes which are not necessarily common to the other areas of robotics. This section first explains similarities and differences in robotics and biology research, and then introduces a set of important concepts, methodology, and research tools often used in the bio-inspired robotics.

75.2.1 Similarities and Differences in Robotics and Biology

Both robotics and biological research aim to obtain the basic understanding about autonomous and adaptive behaviors of complex systems, thus the scientific methodologies of these fields are usually very similar. For example, biologists usually start with finding an interesting problem in animals, that can be comparable to roboticists building robot prototypes of their interests as the first step of research. Second, the animals are carefully observed such that the underlying mechanisms can be efficiently and effectively analyzed, a step which roboticists also follow in the case of their robots. And finally, both biologists and roboticists develop hypothetical models to explain the mechanisms of their interests and test them through additional experiments and analyses. Here the modeling processes are also similar in both robotics and biology in a sense that they typically employ similar scientific methods, such as dynamics modeling tools, computational optimization techniques, and the other analysis methods of system engineering, for example.

There are, however, a number of fundamental differences in biological and robotics research, which are mostly originated in the fact that biological systems are *constructed* by considerably different design principles in nature. Although it is very difficult to cover all differences, the following aspects of biological systems

characterize some of the major discrepancies from today's robotic systems.

Multipurpose Systems in Unstructured and Uncertain Environment

In contrast to most of the robotic systems that are designed to perform one type of task in a well-defined environment, all biological systems are intrinsically multipurpose systems that are designed for many tasks in undefined and uncertain environments. For example, animals need to process tasks such as regulating metabolism for self-sufficiency, protecting themselves from predators, mating, and reproducing. It is important for roboticists to know that (i) animals are not optimized for one of these tasks, but they are designed to conduct all of them, and (ii) they do so in a way that is not optimal in any sense, but just *good enough* to survive and reproduce. Therefore, it is often not a good idea to blindly copy a part of animals' designs and mechanisms into robotic systems because there could be an alternative optimal solution if the system has to do a single task in a well-defined environment. Robotics researchers are, however, able to learn many principles and mechanisms from biological systems, if they are interested in the systems that need to deal with many tasks in unstructured and uncertain environments.

Massively Parallel, Modular, and Redundant Structures

Biological systems are composed of highly redundant structures in their bodies [75.13]. For example, most of multicellular organisms have massively parallel muscle fibers constituting a muscle group, a skeletal joint controlled through multiple muscle groups, millions of nerve cells conducting parallel signal processing, and countless receptors sensing changes in the environment. If compared to our robotic systems today, biological systems have orders of magnitude larger numbers of

such sensory, actuation, and computational units that have to be carefully considered in bio-inspired robotics research. In addition, the processes necessary for autonomy and adaptivity are generally highly decentralized in biological systems. The control of animals' arms and legs, for example, involves mechanical interactions of musculoskeletal structures, reflexive sensory-motor pathways in spinal cord, and more complex motion control and planning in the higher centers of nervous systems, which are running in parallel. The redundant structures of biological systems also provide an important discrepancy between animals and today's robots: most of the subsystems in a living organisms have great autonomy and adaptivity by themselves, as exemplified by the fact that individual cells in skins and bones as well as receptors and muscles have their own regulation mechanisms as metabolism and growth.

Self-Organization and Dynamic Changes of Entire Organisms

Another important discrepancy between animals and today's robots lies in the fact that there is no *human designers* behind animals, and all components in an organism have to be designed, assembled and repaired by itself. Consequently, every individual animal has to start its life smaller and gradually grow larger over time; every part of their bodies is continuously changing; sensory-motor control has to be continuously updated to reflect the changes in the bodies. It is particularly important for robotics researchers to consider that there are different timescales in these dynamic processes in biological systems (Fig. 75.2 [75.16]). Some of the different timescales can be represented by the continuous changes of body plans at the evolutionary processes, the changes of body sizes and muscle strength through ontogenetic timescale, and update of sensory-motor loops in here and now timescale.

75.2.2 Modeling Biological Systems

Modeling plays an essential role in biological sciences. Biological models are the representation of knowledge which is not only used to communicate scientific discoveries among researchers but also structuring research areas by labeling knowns and unknowns. To make research activities efficient and effective, there are many different ways to model biological systems such as descriptive/illustrative explanations, mathematical, physical, or chemical representations. From this perspective, the researchers in bio-inspired robotics have been exploring whether robotic platforms can be used as a scientific tool to develop models of biological systems, which leads to an alternative approach to elucidating biological hypotheses (Fig. 75.3). Robots are

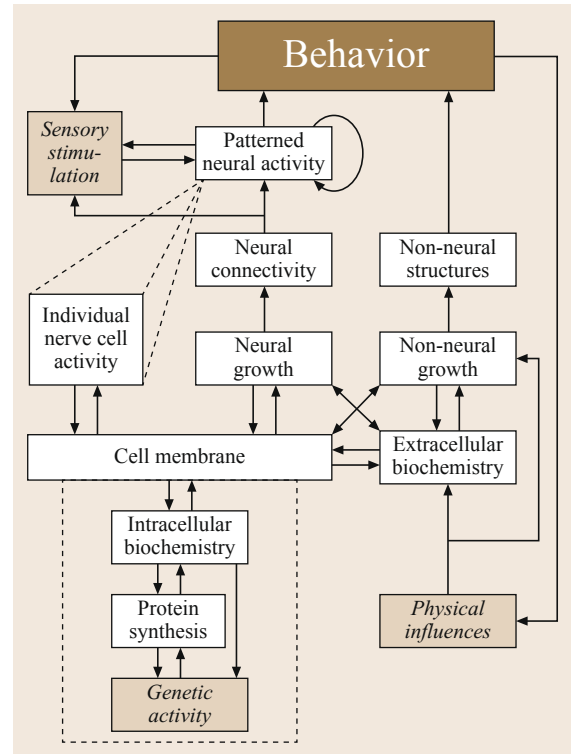

Fig. 75.2 Elements and their interactions that influence behaviors in biological systems. The model includes both neural and non-neural elements such as hormones (which constitute part of the extracellular biochemistry), bones, muscles, sensors, and their ontogenetic processes (after [75.16])

useful because they are physical entities as compared to simulated ones. First of all, by building models that can be implemented in a physical system, the process ensures whether the model in question is physically meaningful or not. In contrast, computationally simulated models always involve many approximations and simplifications which might affect the realism and therefore usefulness of the model (e.g., correctly modeling the hydrodynamics of a swimming fish is very hard in a simulation while it *comes for free* in a fish robot). Second, building robots directly contributes to the development of unconventional technological components.

Having said that, the use of robots as a scientific tool for biology is challenging because of the considerable discrepancies between animals and robots as explained in the previous subsection. A superficial copy of biological systems into a robotic counterpart is not a good idea because robots usually functions based on a completely different set of mechanisms, and the developed robot would most likely not explain much about the underlying mechanisms of biological

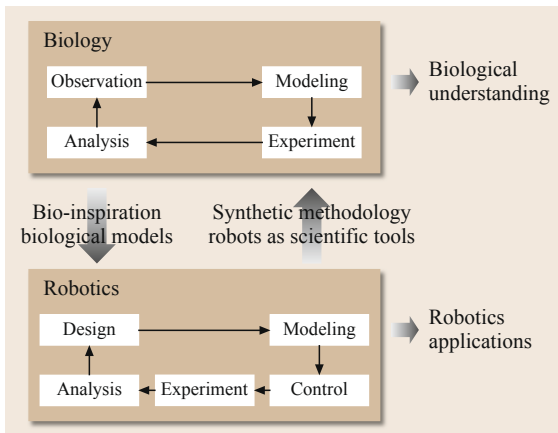

Fig. 75.3 Overview of bio-inspired robotics. Both biology and robotics follow similar research methods and interact to each other through models and tools, while they contribute to different objectives, i. e., understanding of biological systems or development of robotic applications

systems. Instead, it is particularly important to carefully examine what biological hypothesis we are interested in and we are testing by building robotic platforms. As an extreme example, if one is interested in understanding navigation mechanisms of animals, it is usually better to start with wheeled robot platforms than legged or flying ones, because the latter platforms would introduce unnecessary complexity in the research to examine a given hypothesis.

It is, however, not a trivial problem to find good biological hypotheses that can be applied in the bio-inspired robotics research. Biological systems are generally very complex, and hypotheses are not clearly separable from one question to another. Behaviors of animals are, for example, a result from neuronal activi-

ties of short and long terms, musculoskeletal dynamics, genetic and social interactions, and the mechanisms could also significantly vary in different individuals or species.

In order to deal with such a complexity in nature, *Full* and *Koditschek* have proposed an insightful methodology [75.17]. As shown in Fig. 75.4, they proposed a two-level modeling process which could benefit bio-inspired robotics research greatly: in the first level, a model should be simplified as much as possible such that it can be generalized over many species or in a large scale without being bothered too much by the details of complex animal structures. These models are called *templates*. A good example of this kind is the so-called spring-mass model that characterizes running behaviors of many different types of legged animals, even though it is an extremely simple model consisting of a point mass and a linear spring only. This approach enables researchers to examine the basic principles in nature, and despite its simplicity, the model can explain behavioral characteristics in a wide variety of animals even without considering detailed anatomical discrepancies between species. In the second level of modeling processes, templates should be enhanced by more details, which are called *anchors*. The investigations of the anchors are generally intended for more specific questions by adding redundancies of muscles or limbs or implementing more complex neuromuscular circuitry, for example. Through the template-anchor research approach, a research area can be effectively structured, and, for bio-inspired robotics research in particular, the simplified models can benefit robotics engineers to replicate behaviors of biological systems in a conceptual level.

Independently from the simplicity, it is also important to consider the purposes of models which

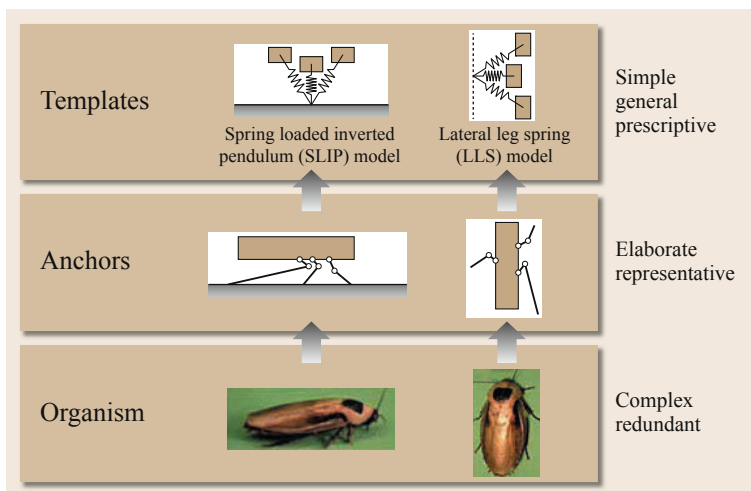

Fig. 75.4 Modeling hierarchy exemplified by the legged locomotion models. Animals can be abstracted into more elaborate and representative models (anchors) and/or simpler and more general models (templates) (after [75.17])

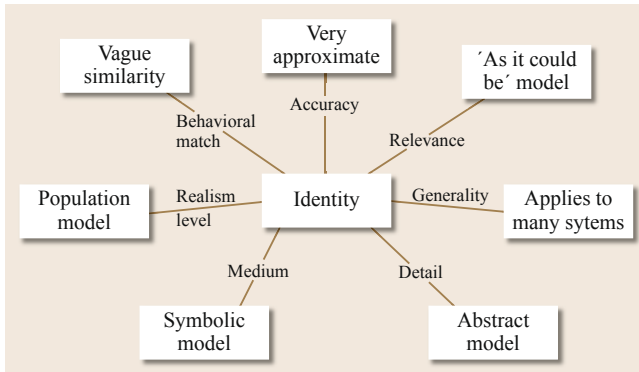

Fig. 75.5 Dimensions for describing models (after [75.18])

also influence how to structure bio-inspired robotics projects. After all, there is no correct model, but there are good or bad models with respect to the goal and hypothesis that are investigated. Webb has, for example, pointed out that there are seven major criteria with which we could evaluate models of bio-inspired robotics (Fig. 75.5 [75.18]):

1. Relevance to biology: as not all robotics research contributes to biological studies, it is important to clarify the degree to which a target robotic system and model are relevant.
2. Level: what are the base units of the model, and on what level of hierarchy in biological systems does the model attempt to represent?
3. Generality: a model could be developed for elucidating a mechanism of a specific system of interest, or for a more general mechanism that can be applied to many others. Therefore, the generality criterion considers how many systems the model intends to represent?
4. Abstraction: this criterion concerns the number and complexity of mechanisms included in the model.
5. Structural accuracy: there are many ways of representing systems but a question is the degree to which the model explains the internal mechanism of the target systems. In an extreme case, a model can behave the same at the level of input/output relationship, but it does not necessarily mean that the internal mechanism is the same.
6. Behavioral match: to what extent does the model behave like the target animal?
7. Medium of model: what is the model built from? A model can be made of mechanical, electrical, hydraulic, etc. or alternatively iconic, analog, symbolic, for example. Properly identifying these questions and the purpose of a robot is important. Indeed, there is a risk in bio-inspired robotics that a project is not useful to biology (i.e., it does

not properly address a scientific question) nor to robotics (i.e., it does not perform better than a more conventional robot).

75.2.3 Research Methods and Tools

As it might have been already noticed, robotics technologies are used for many different purposes in the context of bio-inspired robotics. Robots are often used to *explore* new research areas and questions; many platforms were built and examined for the purpose of *testing biological hypotheses*; some of the other platforms were developed specifically for *application discovery* based on the identified principles in biological studies; and more recently, robotics technologies were *interfaced with or integrated into biological systems* to understand or enhance animals capabilities.

Even though there are many successful contributions of robotics technologies to biological studies, it is often not trivial to identify what are the good methods and tools for the given specific hypothesis or problems. In particular, one of the most critical questions is probably whether it is necessary to build a physical robotic platform or it is sufficient to investigate pseudo-robots in simulation. Building physical robots is usually very costly and requires significant amount of additional knowledge and know how; thus there are many case studies of bio-inspired robotics research conducted only in simulation in the past [75.19, 20]. This type of research generally makes use of physics models or physically realistic simulation environments that allow us to explore fairly complex artificial creatures. This approach is useful to explore a large parameter space which cannot be optimized in the real-world platforms. Also, the use of virtual creatures in the bio-inspired robotics research is also extremely important to investigate concepts and hypotheses that are not possible to test technologically such as robots with point masses, frictionless joints, self-replication, and robotic hardware evolution that cannot be possible with our today's technologies.

However, building physical robots is a *must* in some cases. For example, there are often target concepts or hypotheses involved in physical processes that are difficult to theoretically model, such as friction, impacts, thermodynamics, and hydro/aerodynamics. In addition, there has been an increasing interest in complex robotic systems that contain a considerable number of physical elements such as joints and actuators, simulation models of which tend to be vulnerable against accumulated errors. Another aspect of robots used as a scientific tool is to explore hypotheses that cannot be tested in nature. This approach is often called synthetic methodology (an understanding-by-building approach [75.13]), meaning

that, by building and using artificial systems, we test biological principles that cannot be tested in conventional biological methods. The most representative example is the Braitenberg Vehicles, which we introduced in Sect. 75.1.1. Every vehicle has a set of oversimplified neural connections of an *animal* which does not exist in nature, but these creatures can explain important principles in biological systems. A similar approach was also

extended to the studies of *life as it could be* [75.21, 22], in which, by creating biological phenomena in simulation or robots, a broader and more universal understanding of living systems. This methodology is particularly effective in the studies related to evolutionary biology, in which verifications of hypotheses are usually very challenging ([75.20, 23]; see also the chapter of evolutionary robotics).

75.3 Case Studies

This section introduces three research areas that have been particularly active in bio-inspired robotics in the last few decades. Here we highlight the case studies in which robotics researches contributed to our further understanding of biological systems, and we illustrate how the concepts and methods we introduced in the previous sections were applied to these studies.

75.3.1 Bio-Inspired Legged Locomotion

Legged locomotion has been one of the most popular research topics in bio-inspired robotics for a long time because it characterizes the salient differences between biological and artificial systems. Although legged locomotion is seemingly easy, useful, and efficient for biological systems to move around in complex environments, it is surprisingly difficult to understand the underlying mechanisms hence challenging to implement into robotic systems. The legged locomotion research has a relatively long history that goes back to the foundation of biomechanics in the seventeenth century [75.24], and it became particularly popular when the modern robotics was established in the 1970s [75.25, 26]. One of the main reasons that many robotics researchers were attracted by the issue of legged locomotion lies in the fact that it covers many of the discrepancies between biological and artificial systems that we discussed in Sect. 75.2.1. More specifically, legged systems have to carry out many different tasks in unstructured environments such as establishing sturdy footholds, avoiding obstacles, dealing with variations of payload and velocities, and changing gait patterns, for example; Legged systems have to deal with massive parallel processes which are required for coordinating many joints and muscles, as well as local reflexes and high-level decision and planning; And adaptivity is essential for legged systems because they need to maintain mobility in different environments as well as under significant changes of its body plan over growth processes, for example. While there are countless case studies in the past, this subsection focuses on the four key challenges of bio-inspired

legged locomotion, i. e., stability, gait, energetics, and actuation, because they have been recognized as the long-standing challenges in bio-inspired legged locomotion. More comprehensive robotics research can be found in the section of legged locomotion.

Stability and Gait in Legged Locomotion

One of the main challenges in the study of legged locomotion is to uncover the mechanisms of motion stabilization against disturbances [75.27]. Biological systems usually make use of a variety of mechanisms including mechanical self-stabilization [75.28, 29], spinal reflexes [75.30, 31], central pattern generators [75.32], or sensory-motor control originated in the higher center of nervous system [75.33]. Because of the complexity of stabilization mechanisms in animals, bio-inspired robotics played an important role to systematically investigate the issues of stabilization through modeling of locomotion dynamics and reproducing the behaviors in legged robots of various kinds in the past.

Among others, bipedal walking was one of the most intensively studied topic areas which nicely illustrates how a synthetic approach could structure a research area of a complex biological problem. The backbone of this research area is the so-called *inverted pendulum walking model* which was originally investigated in biomechanics, and later used in the bio-inspired robotics research. The model considers the simplest physics representation of walking dynamics, i. e., a point mass is attached on a massless link, and simulates walking dynamics as the mass vaulting over the link [75.24]. This model can be, for example, physically implemented by the so-called rimless wheel that is the simplest *robotic* representation of the model (Fig. 75.6a; [75.34, 43]), and then, a slightly more complex configuration, the *compass gait model*, was proposed (Fig. 75.6b, [75.44];  VIDEO 111 shows an experiment of a compass gait bipedal robot locomotion on rough terrains). In contrast to the rimless wheel model that considers only stance leg dynamics during walking, the compass gait model has three masses with a passive hip joint, which allow us to investigate swing leg dynamics in addition to the stance

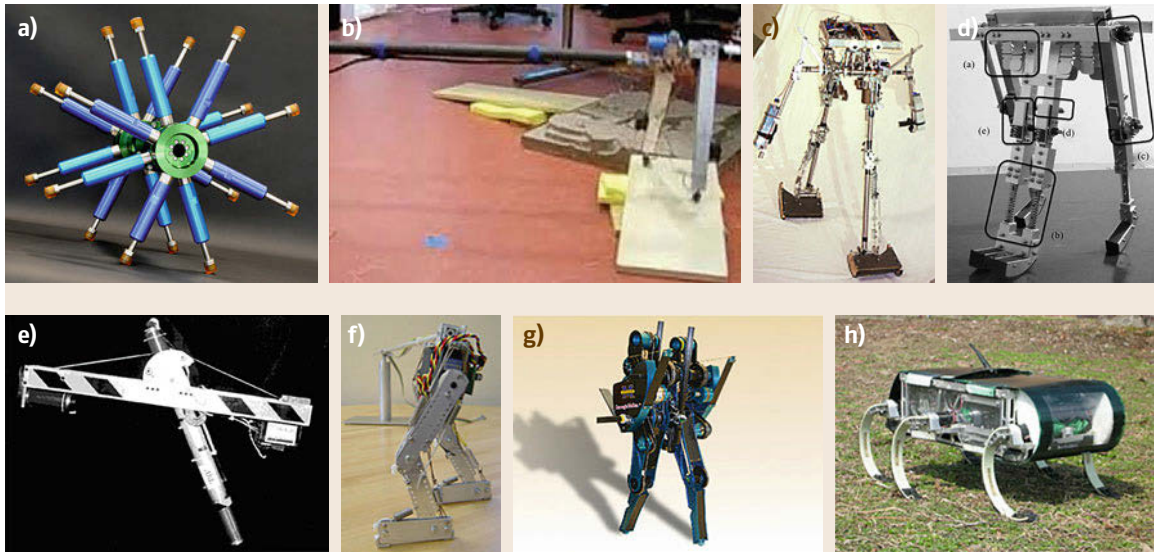

Fig. 75.6a–h Examples of bio-inspired legged robots. (a) A physical implementation of rimless wheel walking model (after [75.34]), (b) A physical implementation of compass gait walking model (after [75.35, 36]), (c) passivity based bipedal walking robot (after [75.37]), (d) passive dynamic runner (after [75.38]), (e) energy efficient hopping robot (after [75.39]), (f) bipedal walking and running robot based on biarticular springs (after [75.40]), (g) biped robot based on variable stiffness actuators (after [75.41]), and (h) hexapod robot based on spring mass dynamics (after [75.42])

leg [75.45]. An important implication of this line of research lies in the fact that, because of the simple formulations of complex dynamics, researchers were able to systematically investigate different aspects of the complex behaviors while keeping an overarching structure of research issues. These simple models were, for example, gradually and systematically enhanced by integrating knee and ankle joints (Fig. 75.6c; [75.37, 43]), foot segments with variations of shapes, influences of mass distributions [75.46], influence of lateral motions, as well as a variety of advanced motion control architectures to demonstrate actuated locomotion in more complex environments [75.35, 36, 47, 48].

Although walking dynamics is a highly interesting challenge, the basic locomotion stability in walking is not sufficient to understand legged locomotion in nature, but stability has to be also maintained in different gait patterns, such as running because most of biological systems exhibit a rich variety of gaits. For this reason, running dynamics has also been studied intensively by investigating a simple model, i.e., the so-called spring-loaded inverted pendulum (SLIP model; [75.28, 49, 50]). The model consists of a point mass and a massless linear spring, on top of which many variations were proposed such as running models with nonlinear spring, segmented legs [75.51], swing leg dynamics, upper torso, lateral balancing [75.52], and wheel-like configuration (Fig. 75.6h [75.42]), for example. The SLIP model was also used to study walk-

ing dynamics and gait transitions between walking and running (Fig. 75.6f [75.40, 53]; VIDEO 110 shows an example of a biped robot walking and running). It is important to note that many of these models and robots were developed for the hypotheses difficult to test in biological systems. The biological legs are hardly linear springs but they consist of numerous active and nonlinear components. However, by examining these models and robots, we are able to learn the basic underlying principles such as the degree to which a spring-like behavior of legs could contribute to the stability of walking and running locomotion, for example. In addition, such an abstraction of biological body structures is very practical for robotics research as we are able to design and construct robots based on the underlying principles without replicating complex anatomical structures consisting of organic components.

Energy Efficiency and Bio-Inspired Actuation

Another considerable challenge in the study of bio-inspired legged locomotion is the principles for energy efficiency. It has been known that the locomotion efficiency of biological systems is known to be at least an order of magnitude better than most of the legged robots today but it is not fully understood why biological locomotion is so efficient. The complexity of the energetic problem in legged locomotion is originated in the many possible sources of energy dissipation such as frictional and damping losses in joints and mus-

cles, mechanical impact losses at foot touchdown to the ground, metabolic costs, and energy required for acceleration and deceleration of body parts. Because of such a complexity, the bio-inspired robotics research has been significantly contributing to this problem by building and analyzing, for example, purely mechanical locomotion systems [75.38, 43], underactuated locomotion control [75.35, 37], the use of passive spring and self-excited vibration [75.39, 54], and exoskeleton devices [75.55]. All of these case studies were contributing to a comprehensive understanding of energy efficiency in biological locomotion [75.56], and some of the hypotheses have been analyzed and tested in biological systems.

In addition to the whole body dynamics, energy efficient locomotion has also been investigated at the level of actuation because the muscle-tendon systems play a major role in animals' efficient locomotion. Inspired from the biological models of muscles, this research trend started from the so-called series elastic actuators, which is an actuator unit containing a mechanical spring

being installed in series to an electric motor [75.62]. The implementation of mechanical spring in an electric motor explained the unique characteristics such as storage of kinetic energy to elastic energy, shock absorption to protect mechanical transmission, and force-based feedback control, all of which are favorable for both biological and artificial legged systems. More recently, many researchers have been attempting to enhance the actuation mechanisms with variable stiffness and damping capabilities [75.41, 63] that are also expected to provide valuable insights into the roles of muscle properties in efficient legged locomotion.

75.3.2 Reflexes and Central Pattern Generators

Agility and adaptability of animals' locomotion are not only originated in mechanical dynamics as explained in the previous subsection, but there are also highly complex control systems regulating animals' motions. Usually animals control systems are labeled into four

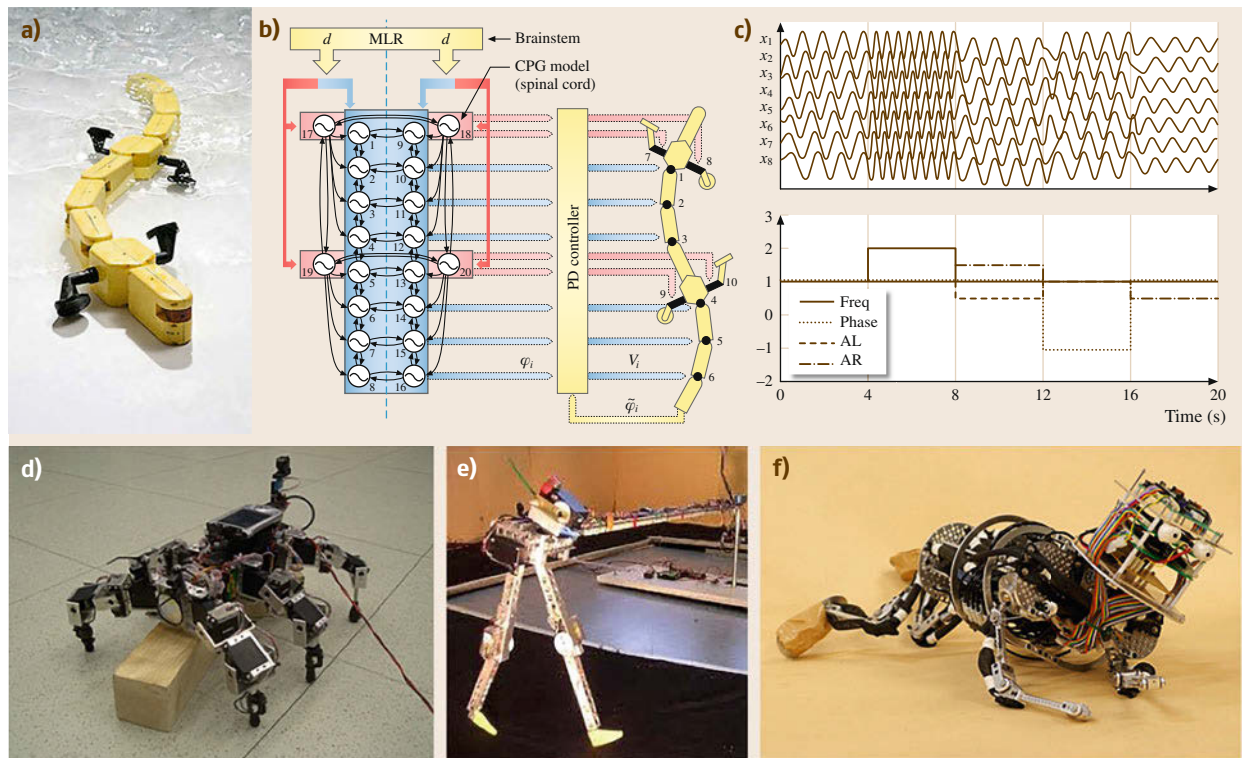

Fig. 75.7a–f Robotic implementation of CPG models. (a) A salamander robot consisting of motorized modules, and (b) its control architecture. Every module has a servomotor which is controlled through a simulated CPG model. (c) Typical behavioral response of the CPG model (upper figure) with respect to a control signal (lower figure). One control input is sufficient to control smooth oscillations of multiple body segments because of coupled dynamics originated in the CPG model (after [75.57]). (d, e) A hexapod and biped robots that use CPG models to adapt to changes in the environment (after [75.58–60]). (f) A musculoskeletal humanoid robot that simulate developmental processes of human babies (after [75.61])

components: the musculoskeletal system, reflexes, central pattern generators (CPGs), and modulation by higher control centers. Bio-inspired robotics has been investigating these components individually or in combination, and resulted in a number of demonstrations of surprisingly robust robot locomotion (Fig. 75.7).

This research area has been historically investigated by the two distinguished approaches, i.e., the CPG-based approach and the reflex-based one. The former approach usually considers voluntary oscillations of neural circuits, that is, CPGs, and the output of these circuits triggers locomotion cycles. Because these behaviors are found in the spinal cord of vertebrate animals and in ganglions in invertebrates [75.64], this approach has been very popular in the bio-inspired robotics. In contrast, the reflex-based approach does not incorporate intrinsic oscillators and generate periodic behavior as a chain of reflex-mediated events. While conceptually different, most of the CPG-based approach considers reflexes in the neural processes; thus these two approaches are often overlapping and reflex-based approaches can be seen as a subset of CPG-based approaches.

One of the pioneering works in the reflex-based approach was based on the neural circuits underlying walking identified in stick insects [75.65, 66]. In this study, it was identified that a series of reflexes for each leg use information related to leg postures and ground contact to generate movements. Coordination between legs (i.e., specific gaits) is obtained with direct neural couplings between individual legs circuits and also through mechanical couplings (e.g., the movement of one limb affecting the load on other limbs). This leads to a decentralized control mechanism, similar in spirit to those developed in behavior-based robotics, that has been validated on simulated and real hexapod robots [75.65, 67].

The reflex-based approach was also investigated in human walking, in which a series of neuromechanical models were developed to demonstrate how the combination of muscle properties and low-level reflexes can lead to stable locomotion in simulated bipeds [75.68, 69]. In particular, Geyer and Herr [75.69] present a simulated bipedal walker which manages to walk in the sagittal plane and to be stable against slight slopes. This model captures principles of neuromuscular feedbacks and predicts muscle activation patterns observed in leg muscles. Similar reflex-based controllers (without muscle models but with simulated synaptic plasticity) have successfully been ported to real robots such as the Runbot [75.60] and the dynamic walkers reported in [75.37].

One of the first examples of the CPG approach has been done in simulation by Taga and colleagues [75.70, 71]. They developed a series of 2-D models of biped locomotion that combine a simple musculoskeletal

model with a CPG modeled as a system of coupled Matsuoka oscillators [75.72]. The work showed how bidirectional couplings between the CPG and the musculoskeletal model could lead to entrainment (i.e., frequency locked regimes) between the two as well as to robust locomotion. Since then a large number of CPG-based controllers have been implemented in robots for different types of locomotion. Examples include hexapod and octopod robots [75.73–75] (see also Robot Roach  VIDEO 112), swimming robots [75.76–78] (see also Salamandra Robotica  VIDEO 113), quadruped robots [75.57, 79, 80], and biped robots [75.81–85].

As discussed in [75.64], a CPG-based approach has several interesting properties:

- i) Stable limit cycle behavior that provides robustness against perturbations.
- ii) Suitability for a distributed implementation.
- iii) Possibility to modulate gaits with a few control parameters.
- iv) Integration of sensory feedback signals in order to obtain mutual entrainment between the CPG and the mechanical body.
- v) Suitable substrate for learning and optimization algorithms. These properties were particularly difficult to investigate by using animals; hence the bio-inspired robotics has provided significant contributions to the nature of motion control in biological systems.

75.3.3 Bio-Inspired Navigation

Biological systems use a variety of cognitive processes for their navigation in complex environment: it is known, for example, that animals use both proprioceptive and exteroceptive receptors for sensing environments; the obtained sensory information is passed to massively parallel processes distributed over many hierarchical levels in central nervous systems; animals' perception of the world is coordinated with low-level sensory-motor processes; and in addition to these mechanisms, long-term planning and learning processes are continuously running to achieve more advanced tasks such as goal-directed navigation. In order to tackle such a complex problem of animals' navigation, bio-inspired robotics also provided a set of effective tools to apply the synthetic methodology some of which are outlined in this subsection.

Sensor Morphology and Sensory-Motor Coordination

A significant number of researchers in bio-inspired robotics have been working on relatively simple animals

such as insects because their central nervous systems are far more tractable than other animals. Despite the simplicity of their brains, insects are incredible navigators being capable of avoiding obstacles while running or flying with enormous speed, recognizing landmarks in unstructured environment, and traveling long distance for foraging. Moreover, some of the social insects can even learn to go back to their own nests, and communicate with co-workers for efficient *community management*. Although biologists have been investigating these fascinating animals for centuries, there are still a number of issues that are not fully clarified yet, and among others, robotics platforms were used to investigate the mechanisms in which physical system–environment interactions play central roles [75.86].

One of the most successful case studies in bio-inspired navigation research was on the mechanisms of sensory-motor coordination in flying insects such as flies and bees. These insects are known to rely on visual sensory information, more specifically, optic flow to detect ego motions, stabilize body posture, measure distance to various objects and landing spots, and track traveling distance, for example. While the visual information processing is usually regarded as computationally expensive, many insects, which have very limited computational resources, make use of this modality to achieve these behavioral functions. The underlying mechanisms are found in the *hardware setups* of animals, in which sensor morphology (i.e., how receptors are distributed) and low-level sensory information processing are exploited in the coordination of sensory-motor processes [75.87]. More specifically, the photoreceptors of these insects are usually distributed to almost all directions which give rise to surprisingly informative stimuli about the environment and ego motions, and low-level neural circuits are configured such that extremely low-processing power is necessary. To test these hypotheses, a number of robotic platforms were developed and tested previously, which showed the feasibility of these mechanisms such as the optic flow to detect nearby objects [75.88], visual odometry [75.89], flight altitude [75.90], and flight stabilization [75.91].

Technological advances are essential to gain additional insights into the complex sensory-motor processes in the animals. At the beginning of the investigations, many researchers developed omni-directional vision based on specifically shaped mirrors attached to regular cameras, while recently more advanced technologies are being developed to flexibly adjust photoreceptors [75.92]. Neuromorphic engineering also provides an additional enabling technology to explore physical foundations of biological nervous systems [75.93, 94]. Neuromorphic silicon retinas are, unlike conventional visual sensors, able to process sensory

information extremely fast and computationally less demanding owing to the event driven and asynchronous processing architectures, while keeping sensitivity very high (i.e., the receptors can be sensitive in very dark environments as well as in a very bright one, [75.95]). With the technological progress, we will be able to reproduce more precise landscape of the world from insects' viewpoint for more comprehensive investigation of bio-inspired navigation.

Goal-Directed Navigation

Compared to reflexive behaviors, goal-directed ones are significantly more complex where much less is known even in biology. In nature, goal-directed behaviors such as navigation to a nest from a distant location require learning of routes and locations, short- and long-term memories, episodic memories, while flexibly adapting to unstructured and often dynamically changing environments. The underlying mechanisms are related to many different locations in the central nervous systems and they vary one species to another, thus the ongoing researches are essentially driven on the basis of the important findings in biology, rather than developing a unified and generalized framework.

One of the representative case studies on bio-inspired goal-directed navigation was again conducted in relation to insect behaviors (Fig. 75.8): some social insects such as desert ant *Cataglyphis* are known to exhibit the so-called *visual homing* behaviors, in which the animals go back to their nests by using visual cues nearby [75.96]. These insects usually walk randomly when searching for food sources, while they go back straight to the nest by using visual cues. Although the neural basis of these behaviors is not yet identified, the biologists argue that an abstract model, the so-called *average landmark vector* method, explain the insects' behavior fairly accurately. Here it is assumed that insects know the global orientation in the world, and every once in a while, they perceive the direction of foraging behavior stored as vector information. Over time, the animals sum up the vectors so that they can keep track on the direction to the nest while randomly search for the food sources. The biologists have been exploring these behaviors for decades, and the accumulated knowledge and hypothetical models were implemented and tested in physical robot platforms. Unlike most of the simulation experiments, the implementation to the robots helped to test the hypothesis in the real-world desert environment [75.96], or physically implemented in an analog circuitry (see also multimedia material of Analog Robot navigation in  VIDEO 242; [75.97]).

A significantly more challenging problem is to identify the mechanisms of goal-directed behaviors in more complex animals, especially in mammals. There

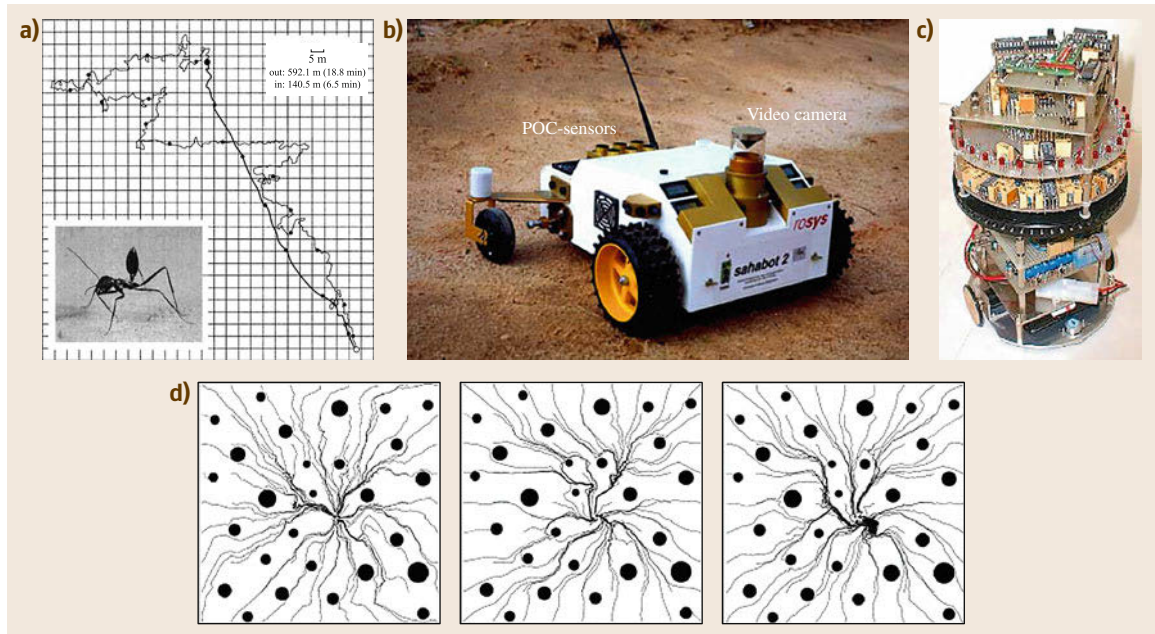

Fig.75.8a–d Visual homing of insect-inspired robots. **(a)** An result of navigation experiment of desert ant *Cataglyphis*. **(b)** A mobile robot Sahabot II that was developed to investigate navigation mechanisms of *Cataglyphis*. The robot is equipped with an omni-directional camera and a digital compass that can be used for the bio-inspired landmark navigation (after [75.96]). **(c)** A fully analog implementation of the visual homing algorithm. **(d)** Simulation results of visual homing algorithm (after [75.97])

is a large body of literature about this issue including cognitive science and brain science, but one of the most prominent contributions of robotic platforms in this research area was to explore neural dynamics during physical system–environment interactions. The research was originally motivated by a discovery in physiology such as the so-called place cells, i. e., a group of neurons in hippocampus exhibit unique behaviors whenever the animal is in a specific location in an environment [75.98]. This hard evidence in neuroscience has been widely used to analyze how brains function in the context of spatial cognition and navigation

in general, including those investigating computational neuroscience and bio-inspired robotics. Essentially, it is still a challenge to explain the behaviors of place cells because they involve sensory-motor activities as well as temporal changes of neural activities (i. e., learning of sensory motor activities) thus a synthetic methodology is extremely helpful. So far it has been shown that the computational models of hippocampus were implemented onto some mobile robot platforms to replicate the behaviors of place cells in navigation tasks [75.99, 100] as well as some more complex goal-oriented behaviors and learning [75.101].

75.4 Landscape of Bio-Inspired Robotics Research and Challenges

So far we introduced only a few representative and ongoing case studies of bio-inspired robotics research, but there are many other active topic areas in the field. Although many of these studies are covered also in the other chapters of this handbook, this section provides a brief overview of the relevant topics in which robotic technologies are being used as scientific tools for biology.

75.4.1 Bio-Inspired Climbing

When legged systems are reduced down to smaller scales, adhesion forces become more dominant than the gravitational, and for this reason, the small-sized animals in nature such as insects, amphibians, and lizards tend to climb terrains rather than walk on level grounds. While the governing physics in the climbing

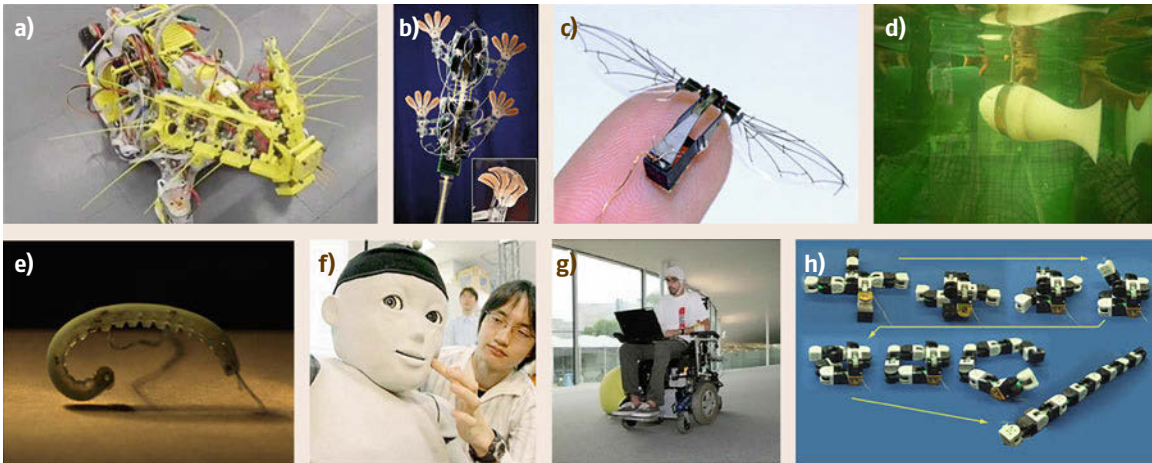

Fig.75.9a–h Examples of recent bio-inspired robots. (a) A mobile robot that uses active whisker arrays for navigation (after [75.102]). (b) A climbing robot based on feet made of dry adhesives (after [75.103]). (c) Micro robot for flapping flight developed by the micro-fabrication techniques (after [75.104]). (d) A fish-like swimming robot that exploits soft continuum body structure (after [75.105]). (e) A worm-like robot that exhibit rolling-locomotion of soft body structure (after [75.106]). (f) A humanoid robot that is equipped with soft skin for interactions with human partners (after [75.107]). (g) A wheel-chair controlled by brain signals of the user (after [75.108]). (h) Self-reconfigurable robot that is capable of autonomously changing its own body structure (after [75.109])

locomotion is different from that of gravity-oriented legged locomotion, robotic platforms are also useful because the dynamics during the locomotion is similarly complex. One of the most representative case studies in this line of research was the use of dry adhesives in climbing robots that are inspired from geckos. Many research topics focused on the fabrication techniques of micro hair-like structures that can generate adhesive forces for a series of small-sized robots (Fig. 75.9b, [75.103, 110]). Similarly a few other approaches were also proposed to explore the different climbing strategies of animals including the use of material-dependent adhesion [75.111], rough-surface locomotion by using feet with micro spine structures [75.112, 113], and climbing strategy based on force closure of relatively long legs [75.114]. There still exist many challenges in fabrication techniques of micro structures in order to replicate the sophisticated climbing mechanisms of animals, which requires continuing close collaborations between researchers in biology and robotics.

75.4.2 Flapping Flight and Swimming Mechanisms

Another complex, yet popular, dynamics used in animal kingdom is fluid/aerodynamics that are typically observed in flying and swimming systems. Fluid/aerodynamics are also dynamics difficult to model and simulate thus robotic platforms are intensively em-

ployed for exploring underlying mechanisms [75.115, 116]. As is the case of walking and running on land, mechanical dynamics also play an important role in flying and swimming locomotion and a number of underactuated robots were developed to understand the nature of locomotion in fluid Fig. 75.9d [75.105, 117]. As the microfabrication techniques evolved in the recent years, roboticists and biologists also started collaborating to investigate small-sized flying robots (Fig. 75.9c, [75.104]; Chap. 26).

75.4.3 Artificial Hands, Haptics, and Whiskers

Haptic perception is known to be one of the most important sensor modalities in biological systems, although the biological nature is far from a comprehensive understanding because animals make use of complex sensory-motor interactions for the purpose of tactile sensing [75.118, 119]. Haptic sensing can be defined as sensing of mechanical environment through *touch* although there are many different variations in nature including tactile sensing through fingers and skins [75.119], active whisking (Fig. 75.9a) [75.102], or more specifically targeted sensing such as slippage detection [75.120]. Exploration on haptic technologies is also crucial in this research area as the biological tactile sensing involves an enormous number of mechanoreceptors each of which has a large sensitivity range. Currently, a number of researchers are actively inves-

tigating technological solutions through haptic devices and soft and stretchable electronics for tactile sensing [75.121, 122].

75.4.4 Self-Reconfigurable and Evolutionary Robotics

Animals' adaptivity in nature relies significantly on their capability of changing their body sizes and structures. Animals are, for example, able to start their lives smaller and gradually grow larger and more complex; they are able to self-repair or regenerate when encountering failures in body parts; and muscles and skins are able to strengthen themselves if necessary [75.123]. Synthetic methodology has also been employed to investigate these fascinating capabilities of biological systems by using, for example, modular robots Fig. 75.9h [75.109, 124, 125], redundant body structures for snake-like motion control [75.126, 127], and self-repair and self-assembly of structures [75.128, 129]. Due to the technological limitations, many researchers take advantage of simulation-based methods to explore the ontogenetic and evolutionary processes to uncover the characteristics of optimization strategies in nature [75.19, 20, 130].

75.4.5 Bio-Inspired Soft Robots

Unlike the conventional robots that are usually made of rigid materials articulated into discrete pieces, animals' body structures mostly consist of soft, continuum,

and elastic components such as muscles, tendons, skins, organs surrounded by smooth membrane [75.1]. Recently, there has been an increasing interest in the use of soft deformable materials in robotic systems to enhance capabilities of, for example, soft locomotion [75.106, 131] ( VIDEO 109 shows an example of soft robot locomotion), manipulation [75.132, 133], shape adaptation [75.134], and soft human–robot interactions [75.63]. Despite its demand in the robotics and biological studies, there are still a number of technological challenges in this field such as soft actuation and sensing [75.135], simulation of soft deformable structures [75.136], and control of flexible continuum bodies [75.137].

75.4.6 Neuroprosthetics and Social Interactions

As we develop more technological components compatible to biological systems, there are more possibilities to implant artificial devices into biological bodies. Although most of the case studies in this research area aim at bio-medical applications as exemplified by visual/auditory prosthetics, pain relief, and motor prosthetics, there are also intensive investigations on the use of prosthetic devices to gain additional insights into the nature of motion control [75.108, 138] and perception [75.139]. There is also an increasing interest in the use of robotic platforms in the studies of social interactions where robots are used to study communications with humans [75.107] and the other animals [75.140].

75.5 Conclusion

This chapter introduced a class of bio-inspired robotics research that is specifically targeted to deepen our understanding of biological systems. Through the representative case studies, we explained how bio-inspired robotics research can be useful not only for developing innovative robots, but also for exploring uncovered challenges in biology by employing the understanding-by-building approach. There are, however, a set of important concepts that need to be considered for successful collaborations between robotics and biology. Specifically:

1. It is necessary to take the similarities and differences in robots and animals into account.
2. There are different goals and methods to develop models of biological systems.
3. The use of robots as a scientific tool has both advantages and disadvantages.
4. There are types of hypotheses in biology that bio-inspired robotics can be particularly beneficial for.

And finally, we also introduced a concise landscape of trends and challenges in bio-inspired robotics. As mentioned earlier, the field of bio-inspired robotics is very broad, and the outline introduced in this chapter is by no means complete. For example, although this chapter only focused on the types of research which contribute to biological studies, there is a large body of the literature on *bio-inspired robotic applications* which are mostly ignored in this chapter. The interested readers should refer to the other chapters in this handbook as well as the other review articles in the field. Also, there are significantly more case studies available in literature which reported on the different species or the other aspects of animals which were summarized in [75.15, 18, 64].

76. Evolutionary Robotics

Stefano Nolfi, Josh Bongard, Phil Husbands, Dario Floreano

Evolutionary Robotics is a method for automatically generating artificial brains and morphologies of autonomous robots. This approach is useful both for investigating the design space of robotic applications and for testing scientific hypotheses of biological mechanisms and processes. In this chapter we provide an overview of methods and results of Evolutionary Robotics with robots of different shapes, dimensions, and operation features. We consider both simulated and physical robots with special consideration to the transfer between the two worlds.

Evolutionary robotics is a method for the automatic creation of autonomous robots [76.1]. It is inspired by the Darwinian principle of selective reproduction of the fittest, captured by evolutionary algorithms [76.2]. In evolutionary robotics, robots are considered as autonomous artificial organisms that develop their own control system and body configuration in close interaction with the environment without human intervention. Drawing inspiration from principles of biological self-organization, evolutionary robotics includes elements

of evolutionary, neural, developmental, and morphological systems. The idea that an evolutionary process could drive the generation of control systems dates back to at least the 1950s [76.3] with a more explicit form appearing in the mid 1980s with the ingenious thought experiments by neuroscientist *Valentino Braitenberg* on neurally driven vehicles [76.4]. In the early 1990s, the first generation of simulated artificial organisms with a genetic code describing the neural circuitry and morphology of a sensory motor system began evol-

ing on computer screens [76.5–8]. At that time, real robots were still complicated and expensive machines that required specialized programming techniques and skillful manipulation. Towards the end of that period, a new generation of robots started to emerge that shared important characteristics with simple biological systems: robustness, simplicity, small size, flexibility, and modularity [76.9,10]. Above all, those robots were

designed so that they could be programmed and manipulated by people without engineering training. Those technological achievements, together with the growing influence of biological inspiration in artificial intelligence [76.11], coincided with the first evolutionary experiments on real robots [76.12–14] (👁️ VIDEO 39 and 👁️ VIDEO 371), and the term evolutionary robotics was coined [76.15].

76.1 Method

The major methodological steps in evolutionary robotics proceed as follows (Fig. 76.1). An initial population of different artificial chromosomes, each encoding the control system (and possibly the morphology) of a robot, is randomly created. Each of

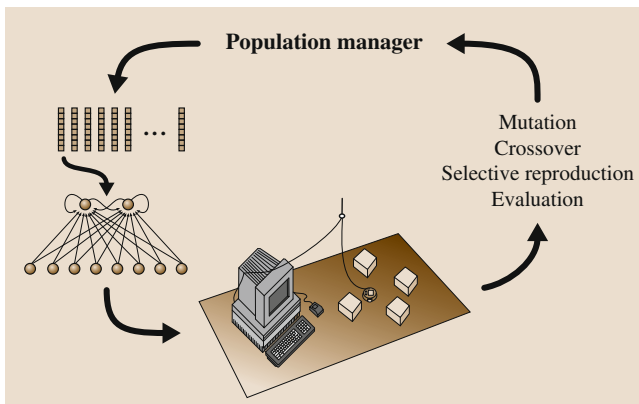

Fig. 76.1 Evolutionary experiments on a single robot. Each individual of the population is decoded into a corresponding neurocontroller which reads sensory information and sends motor commands to the robot every 300 ms while its fitness is automatically evaluated and stored away for reproductive selection

these chromosomes is then decoded into a corresponding controller, for example a neural network (NN), and downloaded into the processor of the robot. The robot is then let free to act (move, look around, manipulate the environment) according to a genetically specified controller while its performance for a given task is automatically evaluated. Performance evaluation is done by a fitness function that measures how fast and straight the robot moves, how frequently it collides with obstacles, etc. This procedure is repeated for all chromosomes of the population. The fittest individuals (those that have received more fitness points) are allowed to reproduce by generating copies of their chromosomes with the addition of random modifications introduced by genetic operators (e.g., mutations and exchange of genetic material). The newly obtained population is then tested again on the same robot. This process is repeated for a number of generations until an individual is born which satisfies the fitness function set by the user. The control system of evolved robots, encoded in an artificial genome, is therefore generated by a repeated process of selective reproduction, random mutation, and genetic recombination, similarly to what happens in natural evolution (👁️ VIDEO 119).

76.2 First Steps

In an early experiment on robot evolution without human intervention, carried out at Ecole Polytechnique Fédérale de Lausanne (EPFL) [76.12], a small wheeled robot was evolved for navigation in a looping maze (Fig. 76.2). The Khepera robot has a diameter of 55 mm and two wheels with controllable velocities in both directions of rotation. It also has eight infrared sensors, six on one side and two on the other side, that can function either in active mode to measure distance from obstacles or in passive mode to measure the amount of (infrared) light in the environment. The robot was con-

nected to a desktop computer through rotating contacts that provided both power supply and data exchange through a serial port (👁️ VIDEO 39).

A simple genetic algorithm [76.16] was used to evolve the synaptic strengths of a neural network composed of eight sensory neurons and two motor neurons. Each sensory unit was clamped to one of the eight active infrared sensors whose value was updated every 300 ms. Each motor unit received weighted signals from the sensory units and from the other motor unit, plus a recurrent connection with itself with a 300 ms

delay. The net input of the motor units was offset by a modifiable threshold and passed through a logistic squashing function. The resulting outputs, in the range $[0, 1]$, were used to control the two motors so that an output of 1 generated maximum rotation speed in one direction, an output of 0 generated maximum rotation speed in the opposite direction, and an output of 0.5 did not generate any motion in the corresponding wheel. A population of 80 individuals, each coding the synaptic strengths and threshold values of the neural controllers, was initialized with all weights set to small random values centered around zero. Each individual was tested on the physical robot for 80 sensorimotor cycles (approximately 24 s) and evaluated at every cycle according to a fitness function with three components measured onboard the robot

$$\phi = V(1 - \sqrt{\Delta v})(1 - i), \quad (76.1)$$

where V is the average rotation speed of the two wheels, Δv is the absolute value of the algebraic difference between the signed speed values of the wheels (positive is one direction, negative the other), and i is the normalized activation value of the infrared sensor with the highest activity. The first component is maximized by speed, the second by straight motion, and the third by distance from objects.

During the first 100 generations, both average and best fitness values grew steadily, as shown in Fig. 76.3. A fitness value of 1.0 would correspond to a robot moving straight at maximum speed in an open space and therefore was not attainable in the looping maze shown in Fig. 76.2, where some of the sensors were often active and where several turns were necessary to navigate. Fig. 76.4 shows the trajectory of the best individual of the last generation.

Although the fitness function did not specify in what direction the robot should navigate (given that it

was perfectly circular and that the wheels could rotate in both directions), after a few generations all the best individuals moved in the direction corresponding to the side with the highest number of sensors. Individuals moving in the other direction had a higher probability of colliding into corners without detecting them and thus disappeared from the population. Furthermore, the cruising speed of the best evolved robots was approximately half of the maximum speed that could be technically achieved and did not increase even when the evolutionary experiment was continued up to 200 generations. Further analysis revealed that this self-limitation of the navigation speed had an adaptive function because, considering the sensory and motor

Fig. 76.3 Average fitness of the population and fitness of the best individual at each generation (error bars show standard error over three runs from different initial populations)

Fig. 76.2 Bird's-eye view of the desktop Khepera robot in the looping maze

Fig. 76.4 Trajectory of the robot with the best neural controller of the last generation. Segments represent the axis between the two wheels. Data were recorded and plotted every 300 ms using an external laser positioning device

refresh rate together with the response profile of the distance sensors, robots that traveled faster had a higher risk of colliding with walls before detecting them; they gradually disappeared from the population.

Despite its simplicity, this experiment shows that evolution can discover solutions that match not only the computational requirements of the task to be solved, but also the morphological and mechanical properties of the robot in relation to its physical environment.

76.2.1 Evolution of Neural Controllers for Walking

Over the past 20 years or so, there has been a growing body of work on evolving controllers for various kinds of walking robots – a nontrivial sensorimotor coordination task. Early work in this area concentrated on evolving dynamical network controllers for simple (abstract) simulated insects (often inspired by cockroach studies) which were required to walk in simple environments [76.17, 18]. Earlier, *Beer et al.* had introduced a neural architecture for locomotion based on studies of cockroaches [76.19], which is shown in Fig. 76.5. The promise of this work soon led to versions of this methodology being used on real robots. Probably the first success in this direction was by *Lewis et al.* [76.14, 20] who evolved a neural controller for a simple hexapod robot using coupled oscillators built from continuous-time, leaky-integrator, artificial neurons. All evaluations were done on the actual robot with each leg connected to its own pair of coupled neurons, leg swing being driven by one neuron and leg elevation by the other. These pairs of neurons were cross connected, in a manner similar to that used by *Beer and Gallagher* [76.18] (Fig. 76.5), to allow coordination between the legs. In order to speed up the process, they employed staged evolution where first an oscillator capable of moving a leg was evolved and then an architecture based on these oscillators was further evolved to develop walking. The robot was able to execute an efficient tripod gait on flat surfaces.

Gallagher et al. [76.21] described experiments where neural networks controlling locomotion in an artificial insect were evolved in simulation and then successfully downloaded onto a real hexapod robot. This machine was more complex than *Lewis et al.*'s, with a greater number of degrees of freedom per leg. In this approach, each leg was controlled by a fully connected network of five continuous-time, leaky-integrator neurons, each receiving a weighted sensory input from that leg's angle sensor. Initially the architecture shown in Fig. 76.5 was used, with the connection weights and neuron time constants and biases under genetic control. This produced efficient tripod gaits for walking on flat

surfaces. In order to produce a wider range of gaits operating at a number of speeds such that rougher terrain could be successfully negotiated, a different distributed architecture, more inspired by stick insect studies, was found to be more effective [76.22].

Galt et al. [76.23] used a genetic algorithm to derive the optimal gait parameters for a Robug III robot, an eight-legged, pneumatically powered walking and climbing robot. The individual genotypes represented parameters defining each leg's support period and the timing relationships between leg movements. These parameters were used as inputs to a mechanistic finite-state machine pattern-generating algorithm that drove the locomotion. Such algorithms, which are often used in conventional walking machines, rely on relatively simple control dynamics and do not have the same potential for the kind of sophisticated multigait coordination that complex dynamical neural network archi-

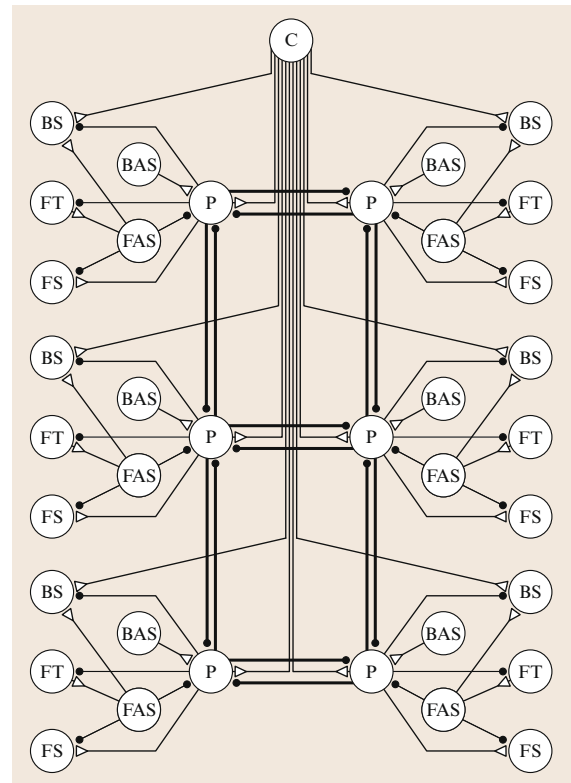

Fig. 76.5 Schematic diagram of a distributed neural network for the control of locomotion as used by *Beer et al.* [76.19]. Excitatory connections are denoted by open triangles and inhibitory connections are denoted by filled circles. C, command neuron; P, pacemaker neuron; FT, foot motor neuron; FS and BS, forward swing and backward swing motor neurons; FAS and BAS, forward and backward angle sensors

tures, such as those described in this section, have been shown to produce. However, controllers were successfully evolved for a wide range of environments and to cope with damage and systems failure (although an individual controller had to be tuned to each environment; they were not able to self-adapt across a wide range of conditions). Gomi and Ide [76.24] evolved the gaits of an eight-legged robot (Fig. 76.6) using genotypes made of eight similarly organized sets of genes, each gene coding for leg motion characteristics such as the amount of delay after which the leg begins to move, the direction of the leg's motion, the end positions of both vertical and horizontal swings of the leg, and the vertical and horizontal angular speed of the leg. After a few dozen generations, where evaluation was on the robot, a mixture of tetrapod and wave gaits was obtained. Using the cellular encoding [76.25] developmental approach – which genetically encodes a grammar-tree program that controls the division of cells growing into a dynamical recurrent neural network of the kind used by Beer et al. – Gruau and Quatramaran [76.26] evolved a single-leg neural controller for the same eight-legged robot used by Gomi and Ide. This generated a smooth and fast quadrupod locomotion gait (📺 VIDEO 372 and 📺 VIDEO 373). Kodjabachian and Meyer [76.27] extended this work to develop more sophisticated locomotion behaviors. Jakobi [76.28] successfully used his minimal simulation techniques (described in Sect. 76.3) to evolve controllers for the same eight-legged robot as Gruau. Evolution in simulation took less than 2 h on what would today be regarded as a very slow computer, and was then successfully transferred to the real robot. Jakobi evolved modular controllers based on Beer's continuous recurrent networks to control the robot as it engaged in walking about its environment, avoiding obstacles and seeking out goals depending on the sensory input. The robot could smoothly change gait, move backward and forward, and even turn on the spot. More recent work has used similar architectures to those explored by the researchers mentioned above, to control more mechanically sophisticated robots such as the Sony Aibo [76.29].

Recently there has been successful work on evolving coupled oscillator style neural controllers for the highly unstable dynamic problem of biped walking. Reil and Husbands [76.30] showed that accurate physics based simulations employing physics-engine software could be used to develop controllers able to generate successful bipedal gaits (📺 VIDEO 374). Reil et al. have now significantly developed this technology to exploits its commercial possibilities, in the animation and games industries, for the real-time control of physically simulated three-dimensional (3-D)

Fig. 76.6 The octopod robot built by Applied AI Systems Inc.

humanoid characters engaged in a variety of motor behaviors (refer to [76.31] for further details). Coupled neural oscillators have been evolved also to control the swimming pattern of articulated, snake-like, underwater robots using physics-based simulations [76.32].

Vaughan has taken related work in another direction. He has successfully applied evolutionary robotics techniques to evolve a simulation of a 3-D ten-degree-of-freedom bipedal robot. This machine demonstrates many of the properties of human locomotion. By using passive dynamics and compliant tendons, it conserves energy while walking on a flat surface. Its speed and gait can be dynamically adjusted and it is capable of adapting to discrepancies in both its environment and its body's construction [76.33]. Parameters describing the body shape (leg segment lengths, hip width, etc.) and properties of a continuous dynamical neural network controller were under genetic control. The machine started out as a passive dynamic walker [76.34] on a slope, and then throughout the evolutionary process the slope was gradually lowered to a flat surface. The machine demonstrated resistance to disturbance while retaining passive dynamic features such as a passive swing leg. Wischmann and Passemann independently took a very similar approach [76.35]. Vaughan's original machine did not have a torso, but he has also successfully applied the method to a simplified two-dimensional (2-D) machine with a torso above the hips. When pushed, this dynamically stable bipedal machine walks either forward or backwards just enough to release the pressure placed on it. It is also able to adapt to external and internal perturbations as well as variations in body size and mass [76.36]. These biped examples make use of the co-evolution of body morphology and neural controller, an idea also used in

earlier, more abstract, work on evolved bipedal locomotion by *Endo et al.* [76.37]. Although possible changes to the body morphology are quite tightly constrained, nonetheless this aspect was important. This theme is covered in more detail in the later section on Evolving Bodies, which also describes recent examples of evolved walking behaviors in the context of body-brain co-evolution.

McHale and Husbands [76.38, 39] have compared many forms of evolved neural controllers for bipedal and quadrupedal walking machines. Recurrent dynamical continuous time networks and GasNets (described

in Sect. 76.7.3) were shown to have advantages in most circumstances. The vast majority of the studies mentioned above were conducted for relatively benign environments. Notwithstanding this observation, we can conclude that the more complex dynamical neural network architectures, with their intricate dynamics, generally produce a wider range of gaits and generate smoother, more adaptive locomotion than the more standard use of systems based on finite-state machines employing parameterized rules governing the timing and coordination of individual leg movements [76.40].

76.3 Simulation and Reality

Few of the experiments in the previous section were carried out entirely on physical robots because:

1. Evolution may take a long time, especially if it is carried out on a single robot that incarnates the bodies of all the individuals of the evolving population.
2. The physical robot can be damaged because populations always contain a certain number of poorly performing individuals (for example, colliding against walls) by effect of random mutations.
3. Restoring the environment to initial conditions between trails of different individuals or populations (for example, replenishing the arena with objects) may not always be feasible without human intervention.
4. Evolution of morphologies and evolution of robots that can grow during their lifetime is almost impossible with today's technology without some level of human intervention.

For those reasons, researchers often resort to evolution in simulation and transfer the evolved controllers to the physical robot. However, it is well known that programs that work well in simulations may not function properly in the real world because of differences in sensing, actuation, and in the dynamic interactions between robot and environment [76.41]. This *reality gap* is even more evident in adaptive approaches, such as evolutionary robotics, where the control system and morphology are gradually crafted through the repeated interactions between the robot and the environment. Therefore, robots will evolve to match the specificities of the simulation, which differ from the real world. Although these issues clearly rule out any simulation based on grid worlds or pure kinematics, over the last 10 years simulation techniques have dramatically improved and resulted in software libraries that model reasonably well dynamical properties such as friction,

collision, mass, gravity, and inertia [76.42]. These software tools allow one to simulate articulated robots of variable morphology and their environment as fast as, or faster than, real time in a desktop computer.

Nonetheless, even physics-based simulations include small discrepancies that can accumulate over time and result in very different behavior from reality (for example, a robot may get stuck against a wall in simulation whereas it can get free in reality, or vice versa). Also, physics-based simulations cannot account for diversity of response profiles of the individual sensors, motors, and gears of a physical robot. Several methods can be used to cope with these problems and improve the quality of the transfer from simulation to reality.

A widely used method consists of adding independent noise to the values of the sensors provided by the model and to the end position of the robot computed by the simulator [76.43]. Some software libraries allow the introduction of noise at several levels of the simulation. This solution prevents evolution from finding solutions that rely on the specificities of the simulation model. Another method consists in sampling the actual sensor values of the real robot positioned at several angles and distances from objects of different texture. Those values are then stored in a look-up table and retrieved with the addition of noise according to the position of the robot in the environment [76.44]. This method proved to be very effective for generating controllers that transfer smoothly from simulation to reality. A drawback of this sampling method is that it does not scale up well to high-dimensional sensors (e.g., vision) or geometrically complicated objects.

Another method, also known as minimal simulations, consists of modeling only those characteristics of the robot and environment that are relevant for the emergence of desired behaviors [76.45]. These char-

acteristics, which are referred to as base-set features, should be accurately modeled in simulation. Instead, all the other characteristics, which are referred to as implementation aspects, should be randomly varied across several trials of the same individual in order to ensure that evolving individuals do not rely on implementation aspects, but rely on base-set features only. Base-set features must also be varied to some extent across trials in order to ensure some degree of robustness of the individual with respect to base-set features, but this variation should not be so large that reliably fit controllers fail to evolve at all. This method allows very fast evolution of complex robot–environment situations, as in the example of the hexapod walk described in Sect. 76.2.1. A drawback of minimal simulations is that it is not always easy to tell in advance which are the base-set features that are relevant for the desired behavior.

Yet another method consists of the coevolution of the robot (control and/or morphology) and of the simulator parameters that are most likely to differ from the real world and that may affect the quality of the transfer [76.46]. This method consists of coevolving two populations, one encoding the properties of the robot and one encoding the parameters of the simulator. Coevolution happens in several passes through a two-stage process. In stage one, a randomly generated population of robots are evolved in the default simulator and the best individual is tested on the real robot while the time series of sensory values are recorded. In stage two, the population of simulators is evolved to reduce the difference between the time series recorded on the real robot and the time series obtained by testing evolved robots within the simulator. The best evolved simulator is then used for stage one where a new randomly generated population is evolved and the best individual is tested on the real robot to generate the time series for stage

two of simulator evolution. This two-stage coevolution is repeated several times until the error between simulated and real robot behavior is the smallest possible. It has been shown that approximately 20 passes of the two-stage process are sufficient to evolve a good control system that could be transferred to an articulated robot. In that case, the real robot was used to test only 20 individuals.

A recent approach tackles the simulation to reality transfer problem by using a multi-objective formulation of ER in which two main objectives are optimized via a Pareto-based multi-objective evolutionary algorithm: (1) the fitness and (2) the transferability [76.47]. To evaluate the transferability a simulation-to-reality disparity measure was defined in terms of the difference in behavior between simulation and reality for any given controller. This measure is approximated for each member of the population and the method has successfully been demonstrated for walking behaviors [76.47].

Finally, another method consists of genetically encoding and evolving the learning rules of the control system, rather than its parameters (e.g., connection strengths). The parameters of the decoded control system are always initialized to small random values at the beginning of an individual lifetime and must self-organize using the learning rules [76.48]. This method prevents evolution from finding a set of control parameters that fit the specificities of the simulation model, and encourages emergence of control systems that remain adaptive to partially unknown environments. When such an evolved individual is transferred to the real robot, it will develop online its control parameters according to the genetically evolved learning rules and taking into account the specificities of the physical world. This method is described in more detail in Sect. 76.7.2 on evolution of learning.

76.4 Behavior as a Complex Adaptive System

Behavior is a dynamical process resulting from nonlinear interactions (occurring at a fast time rate) between the agent's control system, its body, and the environment [76.49, 50]. At any time step, the environment and the agent–environment relation influence the body and the motor reaction of the agent, which in turn influences the environment and/or the agent–environment relation (Fig. 76.7). Sequences of these interactions lead to a dynamical process where the contributions of the different aspects (i.e., the robot's control system, the robot's body, and the environment) cannot be separated. This implies that even complete knowledge of

the elements governing the interactions provides little insight into the behavior emerging from these interactions [76.51, 52].

An interesting property of evolutionary robotics is that it can enable to synthesize robots displaying a certain behavioral capacity without specifying the manner in which such capacity should be realized and/or the combination of elementary behaviors that should be produced and combined to achieve the desired overall capacity. This allows the evolving robots to discover and exploit behaviors that emerge from the interactions between the robot control system, the robot body and

the environment and/or from the interaction between previously developed behavioral capacities [76.52]. The synthesis and exploitation of emergent properties, in turn, often allows evolving robots to discover solutions that rely on relatively parsimonious control policy and/or body structures.

For an example of how evolving robots can solve an adaptive task on the basis of a simple control policy, thanks to the possibility to exploit properties emerging

Fig. 76.7 Schematization of how: (1) behavior can emerge from several nonlinear interactions, occurring at fast time rates, between the agent's control system, its body, and the environment, and (2) behavior can display a multi-level organization in which the robot/environmental interactions and the interaction between lower-level behaviors give rise to higher level behaviors that later affect the interactions from which they originate

Fig. 76.8 The environment and the robot. The environment consists of an arena of 60×35 cm and contains a cylindrical objects placed at a randomly selected location

from the agent/environmental interactions, let us consider the case of a Khepera robot placed in an arena surrounded by walls (Fig. 76.8) that should evolve an ability to forage by finding and remaining close to a food object (i.e., a cylindrical object) [76.53]. The robot is provided with eight infrared sensors and two motors controlling the desired speed of the two corresponding wheels. From the point of view of an external observer, solving this problem requires robots able to:

1. Explore the environment until an obstacle is detected.
2. Discriminate whether the obstacle detected is a wall or a cylindrical object.
3. Approach or avoid the object depending on the object type.

A detailed analysis of the sensory patterns experienced by the robot indicated that the task of discriminating the two objects is far from trivial since the two classes of sensory patterns experienced by robots close to a wall and close to cylindrical objects overlap significantly. However, robots evolved for the ability to solve this task resorted to a strategy that does not require to explicitly discriminate of the two types of objects [76.53]. This solution (VIDEO 116) consists in reacting to sensory states so that the robot/environmental dynamics converge into a limit cycle near the cylindrical object, in which the robot keep moving forth and back and left and right, and not near a wall (Fig. 76.9).

Fig. 76.9a,b Angular trajectories of an evolved robot close to a wall (a) and to a cylinder (b). The picture was obtained by placing the robot at a random position in the environment, leaving it free to move for 500 cycles, and recording its relative movements with respect to the two types of objects for distances smaller than 45 mm. For sake of clarity, arrows are used to indicate the relative direction, but not the amplitude of movements

The possibility to discover and rely on these forms of emergent behavior allows evolving robots to find computationally simple solutions to apparently complex problems. Indeed, the foraging task described above can be solved by a Khepera robot provided with a simple reactive controller (i.e., a feedforward neural network with eight sensory neurons that encode the state of the corresponding infrared sensors directly connected to two motor neurons that set the desired speed of the two wheels).

76.4.1 Behavior Recombination and Re-Use

Evolving robots can recombine and re-use acquired elementary behavioral capacities to produce higher level behaviors. This has been demonstrated in a series of simulation experiments in which a population of humanoid robots provided with an articulated arm, a camera, and a touch sensor on the palm of the hand, have been evolved for the ability to execute two-words imperative sentences constituted by the combination of three action and three object words (reach, touch, move, red-object, green-object, and blue-object) encoded by six corresponding binary sensors [76.54].

During the evolutionary process the robots were evaluated for the ability to *comprehend* seven out of the nine possible sentences (that can be generated by combining the three action and the three object words) by executing the seven corresponding behaviors. The robots were then post-evaluated also on the other two sentences not experienced during the evolutionary process.

Some of the evolved robots were able to develop the required skills and to generalize their capacities to the two new sentences by executing the appropriate corresponding behaviors (📺 VIDEO 41). Differently from the other individuals, the robots able to generalize where characterized by a hierarchical organization in which the nine behaviors were produced by combining over time a set of elementary behaviors and in which the same elementary behaviors was re-used to produce different high-level behaviors. More specifically the robots able to generalize displayed a reach-X behavior (that consisted in moving the arm toward a red, or green, or blue object), a touch behavior (that consisted in moving the hand until the object is touched irrespectively from the color), and a move behavior (that consists in keep moving the hand also after the object has been touched irrespectively from the color) and combined these lower-level behaviors in a compositional man-

ner to produce the nine required higher-level actions. This means that, for example, the same *reach red-object* behavior was used in combination with the *touch* or the *push* behavior to produce a *touch the red-object* and a *push the red-object* behavior. For other works discussing the emergence and the role of multi-level behavioral organizations see [76.52].

76.4.2 Sensory-Motor Coordination

By acting robots inevitably modify the robot-environmental relation and/or the environment and consequently the stimuli that they will experience next. By exploiting the possibility to actively influence the perceived stimuli through actions, robots can find adaptive solutions based on parsimonious control policies. Artificial evolution constitutes an effective method for discovering such type of solutions that are often hard to imagine from the point of view of a human observer. Indeed, examples of clever use of sensory-motor coordination abounds in the evolutionary robotics literature.

Let us consider, for instance, the case of a Khepera robot endowed with infrared and wheels speed sensors, that can forage by remaining close to large cylindrical objects (food) while avoiding small cylindrical objects (dangers) [76.55]. From a passive perspective, that does not take into account the fact that the robot can self-select useful stimuli through action, the ability to discriminate between sensory stimuli experienced near small and large cylindrical objects requires a relatively complex control policy since the two classes of stimuli strongly overlap in the robot's perceptual space. On the other hand, the exploitation of sensory-motor coordination can allow the robots to simplify the discrimination problem.

Indeed, evolving robots tend to converge on a rather simple solution that consists in circling around the cylindrical objects, as soon as an object is perceived, and in using the differential speed of the left and right wheels sensed during the execution of the object-circling behavior to decide to keep circling around the object (in the case of small differential speeds) or to abandon the object (in the case of large differential speeds). Indeed, the execution of the object-circling behavior allows the robots to experience sensory stimuli on the wheel sensors that are well differentiated for small and large objects. This, in turn, allows them to solve the object discrimination problem with a rather simple but reliable control policy. For other examples see [76.53, 56, 57].

76.5 Evolving Bodies

Most evolutionary robotics experiments – and most robotics experiments in general – assume that the body plan of the robot has already been designed; an optimization method is used to improve the control policy only (The term *body plan* is here used to denote all aspects of a robot's design other than its control policy. Such design considerations include the robot's mechanical layout and material properties as well as its sensor and motor distributions.). This emphasis belies an assumption within the field of robotics, which is that control policy design is non-intuitive and thus should be automated, while choosing an appropriate robot body plan is intuitive and thus can be manually designed.

However, it has been shown that the careful design of the robot's body can have large and desirable impacts on its resulting behavior. For example, proper curvature on the underside of a biped robot's feet (along with other settings) can allow it to walk down a declined plane with no control policy at all [76.58]. Or, that modifications to an anthropomorphic robot arm and hand can facilitate the evolution of active categorical perception [76.59] (Active categorical perception occurs when a robot or animal actively interacts with objects of interest, and the sensory stimulation resulting from this physical interaction allows for categorization of those objects.). These results fit with the view of embodied behavior, as outlined in Fig. 76.7: because behavior arises from the interaction between a robot's body and its environment, alterations to the robot's body will alter the resulting behavior.

This suggests that it is useful to automatically improve not just a robot's control policy but also its body plan. Evolutionary algorithms are a uniquely well suited tool for this task because, unlike many learning methods, they do not make assumptions about the structure of the system being optimized: the length of a robot's leg – or the number of legs – can be evolved just as easily as can the strength of a synaptic connection in an artificial neural network.

76.5.1 Co-Evolving Body and Brains

The Sussex group was the first to demonstrate the evolution of robot morphology: they evolved sensor placements on a physical robot [76.15], although the other aspects of the robot's body plan remain fixed. A year later *Sims* [76.61] demonstrated an evolutionary algorithm that improved the structure and parameters of the robots' body plans and control policies. Although *Sim's creatures* were virtual and operated in a simulated environment, the robots exhibited a wide range of intuitive and non-intuitive body plans that allowed them to swim, walk or compete over a limited resource [76.62].

Funes and Pollack [76.63] demonstrated that it was possible to evolve three-dimensional forms in simulation, build them in reality, and have the physical structure act similarly to the originally-evolved simulated structure. This was followed by work from the same group in which robots evolved in simulation were manufactured as physical robots using 3-D printing technology [76.60] (Fig. 76.10). Although only the plastic frame of the robot was printed and the electronics and battery had to be manually added, this served as a demonstration that, in principle, robot design could be automated using evolutionary algorithms and robot manufacture could be automated using rapid prototyping [76.64].

Since then, a number of research groups have evolved robot body plans and control policies simultaneously for various purposes. Some researchers have adapted this approach for studying biological questions. For example *Long et al.* [76.65] have evolved the stiffness of artificial tails attached to physical swimming robots: robots with tails of differing stiffness have differing abilities to swim fast or turn well. This provides a unique experimental tool for investigating how backbones originally evolved in early vertebrates. *Clark et al.* [76.66] also evolved the material properties of part of a robot fish, but focussed in this case on evolving the stiffness and shape of its fins in simulation. This project had an engineering aim: the evolved fins were

Fig.76.10a,b An example evolved robot from the Golem project [76.60]. (a) The virtual robot, as originally evolved in the simulated environment. (b) The physical robot comprised of a 3-D-printed plastic frame and manually-added electronics

manufactured and tested on a physical robot fish and were found to aid desirable swimming behavior.

Evolutionary algorithms can be used to explore the space of possible robot body plans, but they can also be used to explore metamorphosis, or how a robot's body plan might change over its lifetime. In recent work *Bongard* [76.67] compared two approaches to evolving walking behaviors for upright legged robots (👁️ VIDEO 771). In the first approach, upright legged robots were evolved until successful walking was discovered. In the second approach, locomotion was first evolved for legless, anguilliform robots that gradually grew legs while moving. As evolution proceeded in this second approach, later generations of robots gradually lost this infant legless body plan and instead were born with the upright, legged body plan. It was found that walking evolved for the upright legged robots more rapidly in the second approach, and that the evolved controllers were more robust. The explanation for this result is that the legless robot provides a form of scaffolding that accelerates search: it is easier for evolution to generate locomotion for the legless robot because with the anguilliform body plan the robot cannot fall over (Scaffolding is the phenomenon in which a teacher introduces some aspect into the learner's environment that helps the learner to grasp a concept and then later refine the concept when the scaffold is removed [76.68]. The canonical example of scaffolding is training wheels for bicycles.). This locomotion strategy is then refined subsequently by evolution to successfully control the upright and legged (and thus unstable) robot.

The simultaneous evolution of robot body plans and control policies offers other avenues for investigating the relationship between body, brain and environment. In [76.69] it was found that more complexly-shaped robots were produced when evolved to walk over rough terrain than when evolved to walk over flat terrain (👁️ VIDEO 772). This was due to the fact that robots evolved in rough terrain evolved appendages and hooks to gain purchase between outcroppings and then pull or push themselves forward.

Most recently *Hiller* and *Lipson* [76.70] have demonstrated the evolution of soft robots: this requires evolving not just the control policy of the robot and its physical shape, but also the material properties of each voxel comprising the machine. This allows for complex three-dimensional patterning of soft and rigid material throughout the robot, which can be exploited by evolution to produce locomotion [76.71]. Soft robots are an ideal vehicle for demonstrating the power of evolutionary algorithms: the design and control of such machines is highly nonintuitive, making manual design extremely difficult.

76.5.2 Self-Modeling

The evolution of robot body plans can be useful not just for robot design but also for increasing the adaptivity of a physical robot once it has been designed and deployed. For example in [76.72] it was shown that a physical robot could be equipped with an on-board simulator that the robot could use to continuously evolve models of itself. These self-models reflect the mechanical construction of the robot. This method was found useful for robots that might sustain unanticipated damage such as the mechanical separation of a leg: the robot diagnoses the damage; it then evolves a simulated damaged robot that accurately reflects the physical damage; it evolves a compensatory control policy internally using the simulated, damaged robot; and finally the physical robot uses the internally evolved compensatory control policy to continue moving despite its injury. Figure 76.11 outlines this method.

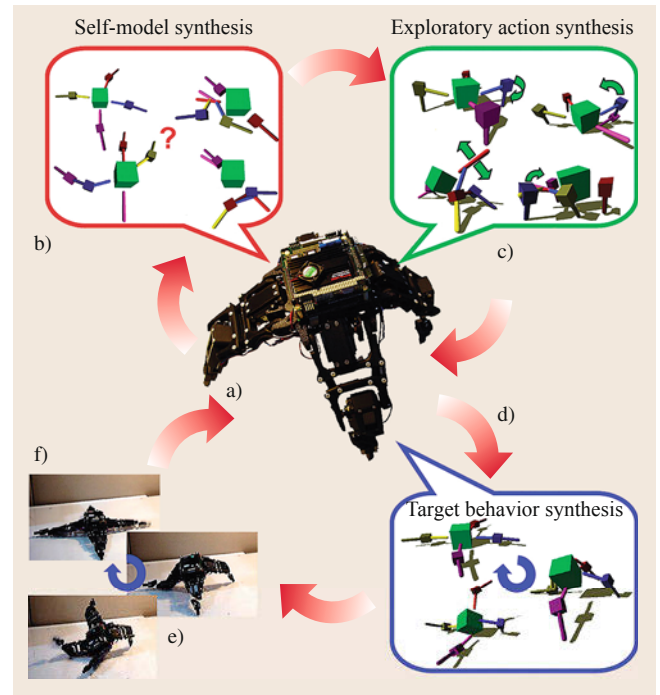

Fig.76.11a–f The machine begins by performing a random action and collects the resulting sensor-motor data (a). An evolutionary algorithm evolves a population of simulated robots that, when they move, produce similar sensor-motor data as the physical machine (b). Another algorithm searches for a new action for the physical robot to perform (c). The physical robot performs the new action, and re-evolves self-models to explain the result of the first action and the new action ((a)). After several cycles of this self-modeling, the best self-model is used to evolve new behaviors (d). Finally, the physical robot executes these newly-evolved behaviors (e,f)

A method for generalizing this to robot swarms was demonstrated in [76.73]. Each robot in the swarm maintained its own self-modeling engine, but would periodically export its best self-model and control policy to others in the swarm. The result of this was that if one robot was damaged and recovered, a second robot that suffered similar damage recovered more rapidly.

Finally, instead of modeling the self, a robot could create a model of another robot in its vicinity. Even bet-

ter, the robot could evolve a model of the other robot's intentions and use this information to aid or thwart the other robot's actions, as demonstrated in [76.74]. Although the robots did not model each other's body plans, this ability to model others in general is known as Theory of Mind. One could imagine how increasing levels of recursion of such embedded mind reading could provide continued evolutionary pressure toward increasingly intelligent machines.

76.6 Seeing the Light

Pioneering experiments on evolving visually guided behaviors were performed at Sussex University [76.75] on a specially designed gantry robot (Fig. 76.12, see also  VIDEO 371). Discrete-time dynamical recurrent neural networks and visual sampling morphologies were concurrently evolved: the brain was developed in tandem with the visual sensor [76.13, 76.77]. The robot was designed to allow real-world evolution by having *off-board* power and processing so that the robot could be run for long periods while being monitored by automatic fitness evaluation functions. A charge-coupled device (CCD) camera points down towards a mirror angled at 45° as shown in Fig. 76.12. The mirror can rotate around an axis perpendicular to the camera's image plane. The camera is suspended from the gantry, allowing motion in the X , Y , and Z dimensions. This effectively provides an equivalent to a wheeled robot with a forward-facing camera when only the X and Y dimensions of translation are used. The additional dimension allows flying behaviors to be studied.

Fig. 76.12 The gantry robot used in the visual discrimination task. The camera inside the top box points down at the inclined mirror, which can be turned by the stepper motor beneath. The lower plastic disk is suspended from a joystick to detect collisions with obstacles

The apparatus was initially used in a manner similar to the real-world experiments on navigation in the looping maze with the miniature mobile robot described in Sect. 76.2. A number of visually guided navigation behaviors were successfully achieved, including navigating around obstacles, tracking moving targets, and discriminating between different objects [76.76]. The evolutionary process was incremental. The ability to distinguish between two different targets was evolved on top of the single target-finding behavior. The chromosome was of dynamic length so the neurocontroller was structurally further developed by evolution to achieve the new task (neurons and connections added). In the experiment illustrated in Figs. 76.12 and 76.13,

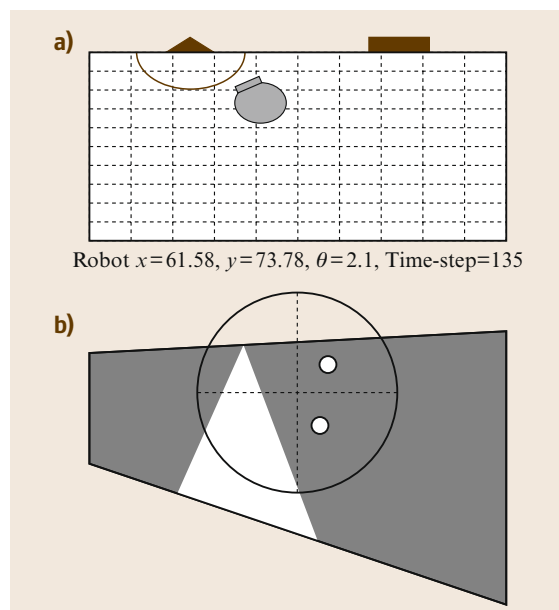

Fig. 76.13a,b The shape discrimination task. (a) The position of the robot in the arena, showing the target area in front of the triangle. (b) The robot camera's field of view showing the visual patches selected by evolution for sensory input

starting from a random position and orientation, the robot had to move to the triangle rather than the rectangle. This had to be achieved irrespective of the relative positions of the shapes and under very noisy lighting conditions. Recurrent neural network controllers were evolved in conjunction with visual sampling morphologies. Only genetically specified patches from the camera image were used (by being connected to input neurons according to the genetic specification). The rest of the image was thrown away. This resulted in extremely minimal systems using only two or three pixels of visual information, yet still able to perform the task reliably under highly variable lighting conditions [76.13, 76].

This was another example of staged, or incremental, evolution to obtain control systems capable of solving problems that are either too complex or may profit from an evolutionary methodology that discovers, preserves, and builds upon subcomponents of the solution. For an evolutionary method that incorporate strategies to explicitly address this issue, interested readers may refer to [76.78]. However, staged evolution remains a poorly explored area of evolutionary robotics that deserves further study and a more principled approach [76.79] in order to achieve increasingly complex robotic systems.

76.6.1 Coevolution of Active Vision and Feature Selection

Machine vision today can hardly compete with biological vision despite the enormous power of computers. One of the most remarkable – and often neglected – differences between machine vision and biological vision is that computers are often asked to process an entire image in one shot and produce an immediate answer whereas animals take time to explore the image over time, searching for features and dynamically integrating information over time.

Active vision is the sequential and interactive process of selecting and analyzing parts of a visual scene [76.80–82]. *Feature selection* instead is the development of sensitivity to relevant features in the visual scene to which the system selectively responds, e.g., [76.83]. Each of these processes has been investigated and adopted in machine vision. However, the combination of active vision and feature selection is still largely unexplored. An intriguing hypothesis is that coevolution of active vision and feature selection could greatly simplify the computational complexity of vision-based behavior by facilitating each other's task.

This hypothesis was investigated in a series of experiments [76.84] on coevolution of active vision and feature selection for behavioral systems equipped with

a primitive moving retina and a deliberately simple neural architecture (Fig. 76.14). The neural architecture was composed of an artificial retina and two sets of output units. One set of output units determined the movement and zooming factor of the retina, and the other set of units determined the behavior of the system, such as the response of a pattern-recognition system, the control parameters of a robot, or the actions of a car driver. The neural network was embedded in a behavioral system and its input/output values were updated every 300 ms while its fitness was computed. Therefore, the synaptic weights of this network were responsible for both the visual features on which the system based its behavior and for the motor actions necessary to search for those features.

In a first set of experiments, the neural network was embedded in a simulated pan-tilt camera and asked to discriminate between triangles and squares of different size that could appear at any location of a screen (Fig. 76.15a), a perceptual task similar to that explored with the gantry robot described in Sect. 76.5. The visual system was free to explore the image for 60 s while continuously reporting whether the current screen showed a triangle or a square. The fitness was proportional to

Fig. 76.14a–f The neural architecture of the active vision system is composed of: (a) a grid of visual neurons with nonoverlapping receptive fields whose activation is given by (b) the grey level of the corresponding pixels in the image; (c) a set of proprioceptive neurons that provide information about the movement of the vision system; (d) a set of output neurons that determine the behavior of the system (pattern recognition, car driving, robot navigation); (e) a set of output neurons that determine the behavior of the vision system; and (f) a set of evolvable synaptic connections. The number of neurons in each subsystem can vary according to the experimental settings

the amount of correct responses accumulated over the 60 s for several screenshots containing various instances of the two shapes. Evolved systems were capable of correctly identifying the type of shape with 100% accuracy after a few seconds despite the fact that this recognition problem is not linearly separable and that the neural network does not have hidden units, which in theory are necessary to solve nonlinearly separable tasks. Indeed, the same neural network presented with the same set of images and trained with supervised learning, but without the possibility to actively explore the scene, was not capable of solving the task. The evolved active vision system developed sensitivity to vertical edges, oriented edges and corners, and used its movement to search for these features in order to tell whether the shape was a triangle or a square. These features, which are also found in the early visual system of almost all animals, are invariant to size and location.

In a second set of experiments, the neural network was embedded in a simulated car and was asked to drive over several mountain circuits (Fig. 76.15b). The simulator was a modified version of a car race video game. The neural network could move the retina across the scene seen through the windscreen at the driver's seat and control the steering, acceleration, and braking of the car. The fitness was inversely proportional to the time taken to complete the circuits without exiting the road. Evolved networks completed all circuits with time laps competitive to those of well-trained students controlling the car with a joystick. The evolved network started by searching for the edge of the road and tracked its relative position with respect to the edge of the windscreen in order to control steering and acceleration. This behavior was supported by the development of sensitivity to oriented edges.

In a third set of experiments, the neural network was embedded in a real mobile robot with a pan-tilt camera

that was asked to navigate in a square arena with low walls located in an office (Fig. 76.16). The fitness was proportional to the amount of straight motion measured over two minutes. Robots that hit the walls because they watched people or other irrelevant features of the office had lower fitness than robots that could perform long straight paths and avoid walls of the arena. Evolved robots tended to fixate the edge between the floor and the walls of the arena, and turned away from the wall when the size of its retinal projection became larger than a threshold (VIDEO 36). This combination of sensitivity to oriented edges and looming is also found in the visual circuits of several insects and birds.

In a further set of experiments [76.85], the visual pathway of the neural network was augmented by an intermediate set of neurons whose synaptic weights could be modified by Hebbian learning [76.86] while the robot moved in the environment. All the other synaptic weights were genetically encoded and evolved. The results showed that lifelong development of the receptive fields improved the performance of evolved robots and allowed robust transfer of evolved neural controllers from simulated to real robots, because the receptive fields developed sensitivity to features encountered in the environment where they happen to be born (see also the section above on simulation and reality). Furthermore, the results showed that the development of visual receptive fields was significantly and consistently affected by active vision as compared to the development of receptive fields passively exposed to the same set of sample images. In other words, robots evolved with active vision developed sensitivity to a smaller subset of features in the environment and actively tracked those features to maintain a stable behavior.

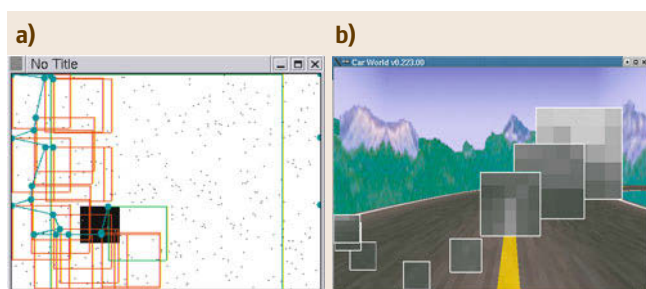

Fig. 76.15 (a) An evolved individual explores the screen searching for the shape and recognizes it by the presence of a vertical edge. (b) Search for the edge of the road at the beginning of a drive over a mountain road

Fig. 76.16 A mobile robot with a pan-tilt camera is asked to move within the walled arena in the office environment

76.7 Computational Neuroethology

Evolutionary robotics is also used to investigate open questions in neuroscience and cognitive science [76.87–90] because it offers the vantage point of a behavioral system that interacts with its environment [76.91]. Although the results should be carefully considered when drawing analogies with biological organisms, evolutionary robotics can generate and test hypotheses that could be further investigated with mainstream neuroscience methods.

For example, the active vision system with Hebbian plasticity described in the previous section was used to answer a question raised by *Held* and *Hein* [76.92] in the 1960s. The authors devised the apparatus shown in Fig. 76.17 where the free movements of a kitten (*active kitten*) were transmitted to a second kitten that was carried in a gondola (*passive kitten*). The second kitten could move its head, but its feet did not touch the ground. Consequently, the two kittens received almost identical visual stimulation, but only one of them received that stimulation as a result of body self-movement. After a few days in that environment, only the active kitten displayed normal behavior in several visually guided tasks. The authors suggested the hypothesis that proprioceptive motor information resulting from generation of actions was necessary for the development of normal, visually guided behavior.

The kitten experiments were replicated by cloning an evolved robot controller and randomly initializing the synaptic values of the adaptive visual pathways in both clones. One cloned robot was then left free to move in a square environment while the other cloned robot was forced to move along imposed trajectories, but was free to control its camera position, just like the passive kitten [76.94]. The results indicated that the visual receptive fields and behaviors of passive robots differ significantly from those of active robots. Furthermore, passive robots that were later left free to move were no longer capable of properly avoiding walls. A thorough analysis of neural activation correlated with behavior of the robot and even transplantation of neurons across active and passive robots revealed that the poor performance was due to the fact that passive robots could not completely select the visual features they were exposed to. Consequently, passive robots developed sensitivity to features that were not functional to their normal behavior and interfered with other dominant features in the visual field. Whether this explanation also holds for living animals remains to be further investigated, but at least these experiments indicated that motor feedback is not necessary to explain the pattern of pathological behavior observed in animals and robots.

76.7.1 Emergence of Place Cells

Let us now consider the case of an animal exploring an environment and periodically returning to its nest to feed. It has been speculated that this type of situation requires the formation of spatial representations of the environment that allow the animal to find its way home [76.95]. Different neural models with various degrees of complexity and biological detail that could provide such functionality have been proposed [76.96, 97].

Would a robot evolved under similar survival conditions develop a spatial representation of the environment and, if so, what type of representation would that be? These questions were explored using the same Khepera robot and evolutionary methodology described in Sect. 76.2 for reactive navigation in the looping maze. The environment was a square arena with a small patch on the floor in a corner where the robot could instantaneously recharge its (simulated) battery (Fig. 76.18). The environment was located in a dark room with a small light tower over the *recharging station*.

The sensory system of the robot was composed of eight distance sensors, two ambient-light sensors (one

Fig. 76.17 The original apparatus in [76.92], where the gross movements of a kitten moving almost freely were transmitted to a second kitten that was carried in a gondola. Both kittens were allowed to move their head. They received essentially the same visual stimulation because of the unvarying pattern on the walls and the center post of the apparatus (after [76.93], with permission)

on each side), one floor-color sensor, and a sensor for battery charge level. The battery lasted only 20 s and had a linear discharge. The evolutionary neural network included five fully connected internal neurons between sensory and motor neurons. The same fitness function described in Sect. 76.2 for navigation in the looping maze was used, except for the middle term which had been used to encourage straight navigation in the looping maze. The fitness value was computed every 300 ms and accumulated over the life span of the individual. Therefore, individuals who discovered where the charger was could live longer and accumulate more fitness by exploring the environment (individuals were killed if they survived longer than 60 s to limit the experimentation time).

The same physical robot evolved for 10 days and nights as both the fitness and life span of individuals continued to increase (Fig. 76.19). After approximately 200 generations, the robot was capable of navigating around the environment, covering long trajectories while avoiding both walls and the recharging area (VIDEO 118). When the battery was almost discharged it initiated a straight navigation towards the recharging area and exited immediately after battery recharge to resume navigation. Best evolved individuals always entered the recharging area one or two seconds before full discharge of the battery. That implies that robots must somehow calibrate the timing and trajectory of their homing behavior depending on where they happened to be in the environment.

In order to understand how that behavior could possibly be generated, a set of neuroethological measures

Fig. 76.18 Bird's eye view of the arena with the light tower over the recharging station and the Khepera robot

were performed using a laser positioning device that provided exact position and orientation of the robot every 300 ms. By correlating the robot position and behavior with the activation of the internal neurons in real time while the evolved individual freely moved in the environment, it was possible to see that some neurons specialized for reactive behaviors, such as obstacle avoidance, forward motion, and battery monitoring. Other neurons instead displayed more complex activation patterns. One of them revealed a pattern of activation levels that depended on whether the robot was oriented facing the light tower or facing the opposite direction (Fig. 76.20). In the former case, the activation pattern reflected zones of the environment and paths typically followed by the robot during exploration and homing. For example, the robot trajectory towards the recharging area never crossed the two *gate walls* visible in the activation maps around the recharging station. When the robot faced the opposite direction, the same neuron displayed a gradient field orthogonally aligned with the recharging area. This gradient provides an indication of the distance from the recharging area. Interestingly, this pattern of activity is not significantly affected by the charge level of the battery.

The functioning of this neuron reminds of the classic findings on the hippocampus of the rat brain where some neurons (also known as *place cells*) selectively fire when the rat is in specific areas of the environment [76.98]. Also, the orientation-specific pattern of neural activation measured on the evolved robot is rem-

Fig. 76.19 (a) Average population fitness (*continuous line*) and fitness of the best individual (*dotted line*). (b) Life span of the best individuals measured as number of sensorimotor cycles, or actions. Individuals start with a full battery which lasts 50 actions (20 s), if not recharged. The maximum life span is 150 actions

inherent of the so-called *head-direction neurons* in the rat hippocampus, which are positioned nearby place cells, whose firing patterns depend on the rat heading direction with respect to an environmental landmark [76.99]. Although the analogy between brains of evolved robots and of biological organisms should not be taken too literally, these results indicate that the two organisms converge towards a functionally similar neural strategy, which may be more efficient to address this type of situation than a strategy that does not rely on representations (but only on reactive strategies such as random motion, light following, or dead reckoning).

76.7.2 Spiking Neurons

The great majority of biological neurons communicate using self-propagating electrical pulses called *spikes*, but from an information-theoretic perspective it is not yet clear how information is encoded in the spike train. Connectionist models [76.100], by far the most widespread, assume that what matters is the *firing rate* of a neuron, that is, the average quantity of spikes emitted by the neuron within a relatively long time window (for example, over 100 ms). Alternatively, what matters is the average number of spikes of a small population of neurons at a give point. In these models the real-valued output of an artificial neuron represents the firing rate, possibly normalized relatively to the maximum attainable value. Pulsed models [76.101], instead, are based on the assumption that the *firing time*, that is, the precise time of emission of a single spike, may convey important information [76.102]. Spiking neuron models have slightly more complicated dynamics of synaptic and membrane integration. Depending on one's theory of what really matters, connectionist or spiking models are used.

However, designing circuits of spiking neurons that display a desired functionality is still a challenging task. The most successful results in the field of robotics obtained so far focused on the first stages of sensory processing and on relatively simple motor control [76.103, 104]. Despite these implementations, there are not yet methods for developing complex spiking circuits that could display minimally cognitive functions or learn behavioral abilities through autonomous interaction with a physical environment.

Artificial evolution represents a promising methodology to generate networks of spiking circuits with desired functionalities expressed as behavioral criteria (fitness function). Evolved networks could then be examined to detect what communication modality is used and how that correlates with observed behavior of the robot.

Floreano and Mattiussi [76.105] evolved a fully connected network of spiking neurons for driving a vision-based robot in an arena painted with black stripes of variable size against a white background (Fig. 76.21). The Khepera robot used in these experiments was equipped with a vision turret composed of one linear array of grayscale photoreceptors spanning a visual field of 36° . The output values of a bank

Fig. 76.20 Activation levels (brightness proportional to activation) of an internal neuron plotted over the environment while the robot was positioned at various locations in each of the four conditions (facing recharging area or not, discharged battery or not). The recharging area is located at the *top left corner* of each map

Fig. 76.21 A network of spiking neurons is evolved to drive the vision-based robot in the arena. The light below the rotating contacts allows continuous evolution also overnight

of local contrast detection filters were converted in spikes (the stronger the contrast, the larger the number of spikes per second) sent to ten fully connected spiking neurons implemented according to the spike response model [76.106]. The spike series of a subset of these neurons was translated into motor commands (more spikes per second corresponded to faster rotation of the wheel). The fitness function was the amount of forward translation of the robot measured over 2 min. Consequently robots that turned in place or hit the walls had comparatively lower fitness than robots that could move straight and turn only to avoid walls. The genome of these robots was a bit string that encoded only the sign of the neurons and the presence of synaptic connections. Existing connections were set to 1 and could not change during the lifetime of the robot.

Evolution reliably discovered very robust spiking controllers in approximately 20 generations, approximately 30 h of evolution on the real robot (VIDEO 37). Evolved robots could avoid not only the walls, but any object positioned in front of them. Detailed analysis of the best evolved controllers revealed that neurons did not exploit time differences between spikes, which one would have expected if optic flow was used to detect distance from walls. Instead, they simply used the number of incoming spikes (firing rate) as an indication of when to turn. When the robot perceived a lot of contrast it would go straight, but when the contrast decreased below a certain threshold (indicating that it approached an object), it started to turn away. This extremely efficient and simple result seems to be in contrast with theories of optic flow detection in insects and may be worth considering as an alternative hypothesis for vision-based behavior.

Spiking neural networks turned out to be more evolvable than connectionist models (at least for this task). One possible explanation is that spiking neurons have subthreshold dynamics that, to some extent, can be affected by mutations without immediately affecting the output of the network.

The robust results and compact genetic encoding encouraged the authors to use an even simpler model of spiking neuron so that the entire neural network could be mapped in less than 50 bytes of memory. The evolutionary algorithm was also reduced to a few lines of code and the entire system was implemented within a programmable intelligent computer (PIC) microcontroller without the need for any external computer for data storage. The system was used for a sugar-cube robot (Fig. 76.22) that autonomously and reliably developed the ability to navigate around a maze in less than an hour [76.107]. Interestingly, evolved spiking controllers developed a pattern of connections where

spiking neurons received connections from a small patch of neighboring sensors, but not from other sensors, and were connected only to neighboring spiking neurons. This pattern of connectivity is also observed in biological systems and encourages specialization of neurons to sensory features.

76.7.3 GasNets

This section describes another style of artificial neural network strongly inspired by those parts of contemporary neuroscience that emphasize the complex electrochemical nature of real nervous systems. In particular, they make use of an analogue of *volume signaling*, whereby neurotransmitters freely diffuse into a relatively large volume around a nerve cell, potentially affecting many other neurons [76.108, 109]. This exotic form of neural signaling does not sit easily with classical pictures of brain mechanisms and is forcing a radical rethink of existing theory [76.110–113]. The class of artificial neural networks developed to explore artificial volume signaling are known as GasNets [76.114]. These are essentially standard neural networks augmented by a chemical signaling system comprising a diffusing *virtual* gas which can modulate the response of other neurons. A number of GasNet variants, inspired by different aspects of real nervous systems, have been explored in an evolutionary robotics context as artificial nervous systems for mobile autonomous robots. They have been shown to be significantly more evolvable, in terms of speed to a good solution, than other forms of neural networks for a variety of robot tasks and behaviors [76.38, 114–116]. They are being investigated as potentially useful engineering tools and as a way of gaining helpful insights into biological systems [76.112, 117–119].

By analogy with biological neuronal networks, GasNets incorporate two distinct signaling mechanisms, one *electrical* and one *chemical*. The underlying *electrical* network is a discrete-time-step recurrent neural network with a variable number of nodes. These nodes

Fig. 76.22 The Alice sugar-cube robot equipped with the evolutionary spiking neural network implemented within its PIC microcontroller

are connected by either excitatory or inhibitory links (Fig. 76.23).

In addition to this underlying network in which positive and negative *signals* flow between units, an abstract process loosely analogous to the diffusion of gaseous modulators is at play. Some units can emit virtual *gases* which diffuse and are capable of modulating the behavior of other units by changing the profile of their output functions. The networks occupy a 2-D space; the diffusion processes mean that the relative positioning of nodes is crucial to the functioning of the network. Spatially, the gas concentration varies as an inverse exponential of the distance from the emitting node with a spread governed by a parameter r with the concentration set to zero for all distances greater than r . The total concentration of gas at a node is determined by summing the contributions from all other emitting nodes.

For mathematical convenience, in the original GasNet there are two *gases*, one whose modulatory effect is to increase the transfer function gain parameter and one whose effect is to decrease it. Thus the gas does not alter the electrical activity in the network directly but rather acts by continuously changing the mapping between input and output for individual nodes, either directly or by stimulating the production of further virtual gas. The general form of the diffusion is based on the properties of a (real) single-source neuron as modeled in detail by Philippides et al. [76.112, 117]. The modulation chosen is motivated by what is known of NO modulatory effects at synapses [76.120]. For full details see [76.114].

Various extensions of the basic GasNet have been produced. Two in particular are strongly inspired by contemporary neuroscience. The *plexus model* is directly inspired by a type of signaling seen in the mammalian cerebral cortex in which the NO signal is generated by the combined action of many fine NO-producing fibers, giving a targeted *cloud* which is distant from the neurons from which the fiber plexus emanates [76.118]. In the plexus GasNet, which models this form of signaling at an abstract level, the spatial distribution of gas concentration has been modified to be uniform over the area of affect. The center of this gas diffusion cloud is under genetic control and can be distant from the controlling node (which, by analogy, is the source of the *plexus*) [76.116]. All other details of the models are identical to the original GasNet model, as described earlier. The *receptor GasNet* incorporates an aspect of biological neuronal networks that has no analog in the vast majority of artificial neural networks (ANNs): the role of receptor molecules. Although neuroscience is a long way from a full understanding of receptor mechanisms, a number of powerful systems level ideas can be abstracted.

Fig. 76.23 A basic GasNet showing positive (solid) and negative (dashed) electrical connections and a diffusing virtual gas creating a *chemical gradient*

Details of the receptor variant are similar to the basic GasNet except there is now *only one* virtual gas and each node in the network can have one of three discrete quantities (zero, medium, maximum) of a number of possible receptors. The modulation the diffusing neurotransmitter affects at a neuron depends on which receptors are present. The strength of a modulation at a node is proportional to the product of the gas concentration at the node and the relevant receptor quantity. In the original GasNet, any node that was in the path of a diffusing transmitter would be modulated in a fixed way. The receptor model allows site-specific modulations, including no modulation (no receptors) and multiple modulations at a single site ([76.116] for further details).

Although most of the GasNet variants described in this section have been successfully used in a number of robotic tasks, their evolvability and other properties were thoroughly compared on a version of the (gantry) robot visual discrimination task described in Sect. 76.5, [VIDEO 375](#). All aspects of the networks were under genetic control: the number of nodes, the connectivity and, in the case of the GasNets, all parameters governing volume signaling (including the position of the nodes and whether or not they were *virtual gas* emitters). The visual sampling morphology was also under evolutionary control. The original basic GasNet was found to be significantly more evolvable than a variety of other styles of connectionist neural networks as well as a GasNet with the volume signaling disabled. Successful GasNet controllers for this task tended to be rather minimal, in terms of numbers of nodes and connections, while possessing complex dynamics [76.114].

Later experiments comparing the basic GasNet with the plexus and receptor variants showed the latter two to be considerably more evolvable than the former, with the receptor GasNet being particularly successful [76.116]. These GasNet experiments demonstrated that the intricate network dynamics made possible by the artificial volume signaling mechanisms can be readily harnessed to generate adaptive behaviors in autonomous agents. They also throw up such questions as why GasNets are more evolvable than many other forms of ANN and why there is a difference in evolvability between GasNet variants. In order to gain insight into what factors are most important in GasNet evolvability, several other varieties were studied, including non-spatial GasNets where the diffusion process is replaced by explicit gas connections with complex dynamics and version with other forms of modulation and diffusion [76.119]. Detailed comparative studies of these variants with each other, and with other forms of ANN, were performed using the visual discrimination task described above [76.116, 119].

The comparative studies revealed that the rich dynamics and additional timescales introduced by the gas played an important part in enhanced evolvability, but were not the whole story [76.116, 119]. The particular form of modulation was also important – multiplicative or exponential modulation (in the form of changes to the transfer function) were found to be effective, but additive modulations were not. The former kind of modulations may well confer evolutionary advantages by allowing nodes to be sensitive to different ranges of input (internal and sensory) in different contexts. The spatial embedding of the networks also appears to play a role in producing the most effective coupling between the two distinct signalling processes (*electrical* and *chemical*). By exploiting a loose, flexible coupling between the two processes, it is possible to significantly reduce destructive interference between them, allowing one to be *tuned* against the other while searching for good solutions [76.115, 116, 121]. Similar forces may be at play in spiking neural networks, where sub-threshold and spiking dynamics interact with each other, which although not yet compared to GasNets, were shown to be more evolvable than connectionist networks. Measurements of the degree of coupling in the GasNets variants versus speed of evolution supported this view [76.116]; the receptor GasNet, for

which the evolutionary search process has the most direct control over the degree of coupling between the signaling processes, and which has a bias towards a loose coupling, was by far the most evolvable [76.116].

Analysis of GasNet solutions often reveals high levels of degeneracy, with functionally equivalent sub-networks occurring in many different forms, some involving gas and some not [76.121]. Their genotype to phenotype mapping (where the phenotype is robot behavior) is also highly degenerate with many different ways of achieving the same outcome (e.g., moving node positions, changing gas diffusion parameters or adding new connections can all have the same effect). This is especially true when variable length genotypes are used to efficiently sculpt solutions in a search space of variable dimensions. The levels of degeneracy are generally significantly higher than when using connectionist networks. These properties partly explain the robustness and adaptability of GasNets in noisy environments and are another important factor in their evolvability (there are many paths to the same phenotypical outcome with reduced probabilities of lethal mutations) [76.119, 122]. In the most successful varieties of GasNet, multi-scale dynamics, modulation and spatial embedding act in concert to produce highly evolvable degenerate networks.

These and ongoing investigations indicate that explicitly dealing with the electrochemical nature of nervous systems is likely to be an increasingly fruitful area of research, both for evolutionary robotics and for neuroscience, that will likely force us to broaden our notions of what behavior-generating mechanisms might look like.

Because of its ability to explore whole classes of underspecified models, ER is being increasingly used to develop or explore neural models aimed at answering specific questions in neuroscience [76.88–90] or to probe new theories about possible neural mechanisms [76.90]. One intriguing recent hypothesis is that one of the forms of plasticity on which the brain relies is itself a form of evolution via natural selection acting within neural tissue [76.123, 124]. The units of selection in this case are activity and connection patterns which are copied between groups of neurons. Irrespective of whether or not it occurs in nature (and it might), this kind of mechanism could be employed in a whole new kind of evolutionary robotics.

76.8 Evolution and Learning

Evolution and learning (or phylogenetic and ontogenetic adaptation) are two forms of biological adaptation that differ in space and time. Evolution is a process

of selective reproduction and substitution based on the existence of a population of individuals displaying variability at the genetic level. Learning, instead,

is a set of modifications taking place within each single individual during its own life time. Evolution and learning operate on different time scales. Evolution is a form of adaptation capable of capturing relatively slow environmental changes that might encompass several generations (e.g., the perceptual characteristics of food sources for a given species). Learning, instead, allows an individual to adapt to environmental modifications that are unpredictable at the generational level. Learning might include a variety of mechanisms that produce adaptive changes in an individual during its lifetime, such as physical development, neural maturation, variation of the connectivity between neurons, and synaptic plasticity. Finally, whereas evolution operates on the genotype, learning affects only the phenotype, and phenotypic modifications cannot directly modify the genotype.

Researchers have combined evolutionary techniques and learning techniques (supervised or unsupervised learning algorithm such as reinforcement learning or Hebbian learning; for a review see [76.125]). These studies have been conducted with two different purposes:

1. Identifying the potential advantage of combining these two methods from the point of view of developing robust and effective robots.
2. Understanding the role of the interaction between learning and evolution in nature.

Within an evolutionary perspective, learning has several different adaptive functions. First, it might allow individuals to adapt to changes that occur too quickly to be tracked by evolution [76.126]. Secondly, learning might allow robots to use information extracted during their interaction with environment to develop adaptive characters ontogenetically without necessarily discovering these characters through genetic variations and without encoding these characters in their genome. To understand the importance of this aspect, we should consider that evolutionary adaptation is based on an explicit but concise indication of how well an individual robot coped with its environment – the fitness value of a robot. Ontogenetic adaptation, on the contrary, is based on extremely rich information – the state of the sensors while the robot interacts with its environment. This huge amount of information encodes very indirectly how well an individual is doing in different phases of its lifetime or how it should modify its behavior to increase its fitness. However, evolving robots that have acquired a predisposition to exploit this information to produce adaptive changes during their lifetime might be able to develop adaptive characteristics on the fly, thus leading to the possibility to

produce *complex* phenotypes on the basis of parsimonious genotypes. Finally, learning can help and guide evolution. Although physical changes of the phenotype, such as strengthening of synapses during learning, cannot be written back into the genotype, *Baldwin* [76.127] and *Waddington* [76.128] suggested that learning might indeed affect the evolutionary course in subtle but effective ways. Baldwin's argument was that learning accelerates evolution because suboptimal individuals can reproduce by acquiring during life necessary features for survival. However, variation occurring during successive generation might lead to the discovery of genetic traits that lead to the establishment of the same characteristics that were previously acquired through lifetime learning. This latter aspect of Baldwin's effect, namely indirect genetic assimilation of learned traits, has been later supported by scientific evidence and defined by *Waddington* [76.128] as a canalization effect.

Learning however, also has costs such as: (1) a delay in the ability to acquire fitness (due to the need to develop fit behavior ontogenetically), and (2) increased unreliability due to the fact that the possibility to develop certain abilities ontogenetically is subjected to partially unpredictable characteristics of the robot–environment interaction [76.129]. In the next two subsections we describe two experiments that show some of the potential advantages of combining evolution and learning.

76.8.1 Learning to Adapt to Fast Environmental Variations

Consider the case of a Khepera robot that should explore an arena surrounded by black or white walls to reach a target placed in a randomly selected location [76.126]. Evolving robots are provided with eight sensory neurons that encode the state of the four corresponding infrared sensors and two motor neurons that control the desired speed of the two wheels. Since the color of the walls change every generation and since the color significantly affects the intensity of the response of the infrared sensors, evolving robots should develop an ability to *infer* whether they are currently located in an environment with white or black walls and learn to modify their behavior during lifetime. That is, robots should avoid walls only when the infrared sensors are almost fully activated in the case of arenas with white walls, while they should avoid walls even when the infrared sensors are slightly activated in the case of arenas with black walls.

Robots were provided with a neural controller (Fig. 76.24) including four sensory neurons that encoded the state of four corresponding infrared sensors;

two motor neurons that encoded the desired speed of the two wheels; and two teaching neurons that encoded the teaching values used to modify the connection weights from the sensory neurons to the motor neurons during the robots' lifetime. This special architecture allows evolving robots to transform the sensory states experienced by the robots during their lifetime into teaching signals that might potentially lead to adaptive variations during lifetime. Analysis of evolved robots revealed that they developed two different behaviors that are adapted to the particular arena where they happen to be *born* (surrounded by white or black walls). Evolving robots did not inherit an ability to behave effectively, but rather a predisposition to learn to behave. This predisposition to learn involves several aspects such as a tendency to experience useful learning experiences, a tendency to acquire useful adaptive characters through learning, and a tendency to channel variations toward different directions in different environmental conditions [76.126].

76.8.2 Evolution of Learning

In the previous example, the evolutionary neural network learned using a standard learning rule that was applied to all synaptic connections. *Floreano* and *Moncada* [76.130] explored the possibility of genetically encoding and evolving the learning rules associated to the different synaptic connections of a neural network embedded in a real robot. The main motivation of this line of work was to evolve robots capable of adapting to a partially unknown environment, rather than robots adapted to the environment(s) seen during evolution. In order to prevent evolutionary tuning of the neural network to the specificities of the evolutionary environment (which would limit transfer to different

Fig. 76.24 A self-teaching network. The output of the two teaching neurons is used as a teaching value for the two motor neurons. The weights that connect the sensory neurons to the teaching neurons do not vary during the robots' lifetime while the weights that connect the sensory neurons to the motor neurons are modified with an error-correction algorithm

environments or transfer from simulation to reality), the synaptic weight values were not genetically encoded. Instead, each synaptic connection in the network was described by three genes that defined its sign, its learning rule, and its learning rate (Fig. 76.25). Every time a genome was decoded into a neural network and downloaded onto the robot, the synaptic strengths were initialized to small random values and could change according to the genetically specified rules and rates while the robot interacted with the environment. Variations of this methodology included a more compact genetic encoding where the learning properties were associated to a neuron instead of a synapse. All synapses afferent to a neuron used its genetically specified rules and rates. Genes could encode four types of Hebbian learning that were modeled upon neurophysiological data and were complementary to each other [76.131].

Experimental results in a nontrivial, multitask environment (Fig. 76.26, [VIDEO 40](#)) indicated that this methodology has a number of significant advantages with respect to the evolution of synaptic strengths without learning [76.48]. Robots evolved faster and obtained better fitness values. Furthermore, evolved behaviors were qualitatively different, notably in that they did not exploit minimal solutions tuned to the environment (such as turning only on one side, or turning in circles tuned to the dimensions of the evolutionary arena). Most important, these robots displayed remarkable adaptive properties after evolution. Best evolved individuals: (1) transferred perfectly from simulated

Fig. 76.25 Two methods for genetically encoding a synaptic connection. Genetically determined synapses cannot change during the lifetime of the robot. Adaptive synapses instead are randomly initialized and can change during lifetime of the robot according to the learning rules and rates specified in the genome

to physical robots, (2) accomplished the task when the light and reflection properties of the environment were modified, (3) accomplished the task when key landmarks and target areas of the environment were displaced, and (4) transferred well across morphologically different robotic platforms. In other words, these robots were selected for their ability to solve a partially unknown problem by adapting on the fly, rather than for being a solution to the problem seen during evolution.

In further experiments where the genetic code for each synapse of the network included one gene whose value caused its remaining genes to be interpreted as connection strengths or learning rules and rates, 80% of the synapses *made the choice* of using learning, reinforcing the fact that this genetic strategy has a comparatively stronger adaptive power [76.131]. This methodology could also be used to evolve the morphology of neural controllers where synapses are created at runtime and therefore their strengths cannot be genetically spec-

Fig. 76.26 (a) A mobile robot Khepera equipped with a vision module can gain fitness points by staying on the *grey area* only when the light is on. The light is normally off, but it can be switched on if the robot passes over the *black area* positioned on the other side of the arena. The robot can detect ambient light and wall color, but not the color of the floor. (b) Behavior of an individual evolved in simulation with genetic encoding of learning rules

ified [76.132]. Recently, the adaptive properties of this type of adaptive genetic encoding were confirmed also in the context of evolutionary spiking neurons for robot control [76.133].

76.9 Evolution of Social Behavior

In the previous sections, we limited our analysis to individual behaviors, i. e., to the evolution of robots placed in an environment that does not include other robots. The evolutionary method, however, can also be applied to evolve social behaviors in which multiple robots situated in the same environment interact between themselves in cooperative or competitive manners.

As we will see, competitive co-evolution is particularly interesting from the point of view of synthesizing progressively more complex capacities and from the point of view of developing solutions that are robust with respect to environmental variations. Cooperative evolution instead is particularly interesting for the possibility to solve problems that cannot be handled by a single robot, because of physical constraints or limited behavioral capabilities [76.134] and to develop solutions that are robust.

76.9.1 Coevolving Predator and Prey Robots

Competitive coevolution, for example the coevolution of two populations of predator and prey robots that are evolved for the ability to catch prey and to escape predators, respectively, has two characteristics that are particularly interesting from an evolutionary robotics perspective. The first aspect is that the competition between populations with different interests might spontaneously lead to a sort of incremental evolutionary process where evolving individuals are faced with

progressively more complex challenges (although this is not necessarily the case). Indeed, in initial generations the task of the two populations is relatively simple because opponents have simple and poorly developed abilities on average. After a few generations, however, the abilities of the two populations increase and, consequently, the challenges for each population become more difficult. The second aspect consists of the fact that the environment varies across generations because it includes other coevolving individuals. This implies that coevolving individuals should be able to adapt to ever-changing environments and to develop behaviors that are robust with respect to environmental variations [76.135].

The potential advantages of competitive coevolution for evolutionary robotics have been demonstrated by a set of experiments conducted by *Floreano* and *Nolfi* [76.136, 137] where two populations of robots were evolved for the ability to catch prey and escape predators, respectively (Fig. 76.27).

The results indicated that both predator and prey robots tended to vary their behavior throughout generations without converging on a stable strategy. The behavior displayed by individuals at each generation tended to be tightly adapted to the counter-strategy exhibited by the opponent of the same generation (VIDEO 38). This evolutionary dynamic however does not really lead to long-lasting progress because, after an initial evolutionary phase, the coevolutionary

Fig. 76.27 Experimental setup. The predator and prey robot (from left to right) are placed in an arena surrounded by walls and are allowed to interact for several trials starting at different randomly generated orientations. Predators are selected on the basis of the percentage of trials in which they are able to catch (i. e., to touch) the prey, and prey on the basis of the percentage of trials in which they were able to escape (i. e., to not be touched by) predators. Predators have a vision system, whereas the prey have only short-range distance sensors, but can go twice as fast as the predator. Collision between the robots is detected by a conductive belt at the base of the robots

Fig. 76.28 An s-bot and a simulated swarm-bot consisting of four s-bots assembled in chain formation

process led to a limit cycle dynamic where the same small set of behavioral strategies recycled over and over again along generations [76.137]. This limit cycle dynamic can be explained by considering that prey robots tended to vary their behavior in order to disorient predators as soon as predators become effective against the current behavioral strategies exhibited by prey robots.

However, experiments [76.138] where robots were allowed to change their behavior on the fly on the basis of unsupervised Hebbian learning rules showed that

the evolutionary phase where coevolving robots were able to produce real progress was significantly longer, and evolved predators displayed an ability to effectively cope with prey exhibiting different behavioral strategies by adapting their behavior on the fly to the prey's behavior. Prey instead tended to display behavior that changed in unpredictable ways.

Further experiments showed that competitive coevolution can solve problem that the evolution of a single population cannot. *Nolfi* and *Floreano* [76.137] demonstrated that the attempt to evolve predators robot for the ability to catch a fixed pre-evolved prey produced lower performance with respect to control experiments where predators and prey were coevolved at the same time.

76.9.2 Evolving Cooperative Behavior

As testified by social insects, colonies of simple cooperating individuals can display remarkable capacities and exhibit self-organising behaviors in which the spatio-temporal pattern observed at the system level emerge from numerous interactions among the individual robots. On the other hand, designing collective robotic systems of this sort constitutes a difficult problem due to the indirect relationship between the desired group behavior and the characteristics of the individual robots. By evaluating the robotic system as a whole (i. e., by selecting the robots on the basis of the global behavior that emerge from a large number of robot/environmental and robot/robot interactions), Evolutionary Robotics provides a means for discovering effective behavioral solutions and simple and robust control policies [76.139].

Recent research showed that teams of evolved robots can:

1. Develop robust and effective coordinated behavior [76.140, 141]
2. Collaborate by assuming complementary role [76.141, 142] ([VIDEO 376](#))
3. Display self-organizing properties [76.143]
4. Develop and use communicative capabilities [76.144–146].

Moreover, some of the research carried in this area demonstrated how evolutionary robotics experiments can contribute to model biological phenomena, e.g., to identify the evolutionary conditions that enable the emergence of cooperative communicative behaviors [76.146] or the mechanisms enabling the evolution of effective division of labour strategies [76.147]

Here we briefly review a series of experiments where swarm-bots [76.148], i. e., groups of autonomous robots capable of assembling by physically connecting together, were evolved for the ability to display coordinated motion ( VIDEO 115). Each individual robot consisted of a main platform (chassis) and turret that could actively rotate with respect to each other (Fig. 76.28). The chassis included tracks with teathed wheels for navigation on both rough and flat terrain, and infrared sensors pointing to the ground. The turret included a gripper, sixteen light-sensors distributed around the body, a loudspeaker, three microphones, and a traction sensor placed between the turret and the chassis to detect the direction and the intensity of the traction force that the turret exerts on the chassis. Swarm-bots were formed by several robots provided with identical neural controllers and assembled together so to form a single physical entity.

By evolving the neural controllers of these Swarm-bots, Baldassare et al. [76.140] demonstrated how the robots can display a robust and effective coordinated capacities that allow the individuals to negotiate and converge on a coherent direction and to keep moving along that direction by compensating the disalignments originating during motion. Such behavioral capacity was robust enough to allow a smooth transfer from simulation to reality and to allow the robots to generalize their capacity to rugged terrains. In an extended experiments in which the s-bots were also equipped with infrared sensors, speakers and microphones, the evolved swarm-bots also showed a capacity to avoid dangers (e.g., holes) by coordinately changing direction as soon as one s-bot detected a hole [76.149].

Evolved swarm-bots generalized their coordinated motion capabilities also when they were tested in different conditions (e.g., when they were assembled in much more numerous groups and/or in different topologies, or when they had to also carry heavy objects by pushing and pulling them in a coordinated manner). Finally, when placed in new environmental conditions (e.g., in environment with obstacle and walls), the swarm-bots spontaneously displayed new behavioral skills (related to acquired skills), such as the ability to cooperatively avoid obstacles, without any further adaptation. This ability to display new related behaviors, in new behavioral conditions, emerged as a result of the dynamical process originating from the interaction of the same robots with the new environmental conditions [76.142, 150].

76.9.3 Evolution of Communication

Communication represents a key aspect in collective behaviors. Recent research in evolutionary robotics has demonstrated how sophisticated communication capabilities can emerge and evolve in population of robots selected for the ability to perform tasks requiring coordination and/or cooperation.

The analysis of these experiments indicate that communicative interactions often originate as the result of cues, that provide useful information to other robots, produced inadvertently during the execution of specific behaviors [76.146, 151]. The presence of these cues create the basis for the development of an ability to react to them in an adaptive way thus leading to the establishment of adaptive communicative interactions in which robots produce signals and react to detected signals adaptively. The establishment of these forms of communicative interactions then create the adaptive conditions for the co-evolution of signalling and response strategies [76.152] ( VIDEO 117).

The reliability and stability of the resulting communication system depend on the level of relatedness (i. e., genetic similarity) between robots and the level at which they were selected [76.146]. Robots that are genetically highly related or that are selected on the basis of the behavior exhibited by the group evolve reliable signals and stable communicative conventions. In contrast, when relatedness between robots is low and selection is acting at the level of the individuals, the evolutionary process might lead to the emergence of instable, ineffective and in some case deceptive communication forms [76.153, 154].

The evolution of communication is strongly interlinked with the evolution of other behavioral capacities [76.155]. Indeed, after all, robots need to develop appropriate behaviors to access and/or generate the information to be communicated and/or to react to detected signals appropriately. The co-adaptation of behavioral and communicative skills might lead to prolonged innovation phases in which the development of behavioral capacities create the adaptive conditions for the development of communication capacities and vice versa [76.151, 152]. Moreover, the co-adaptation of behavioral and communication capacities tend to lead to highly contingent evolutionary processes in which the capacities possessed by the population at a certain evolutionary phase strongly influence the outcome of the successive phases [76.152, 156] ( VIDEO 117).

76.10 Evolutionary Hardware

In recent years, technology advancements have allowed researchers to explore evolution of electronic circuits. In this section, we briefly summarize some foundational work in this direction.

76.10.1 Evolvable Hardware Robot Controllers

In most of the work discussed so far some form of genetically specified neural network, implemented in software, has been at the center of the robot control system. Work on a related approach of evolving control systems directly onto hardware dates back to *Thompson's* work in the mid 1990s [76.157]. In contrast to hardware controllers that are designed or programmed to follow a well-defined sequence of instructions, evolved hardware controllers are directly configured by evolution and then allowed to behave in real time according to semiconductor physics. By removing standard electronics design constraints, the physics can be exploited to produce highly nonstandard and often very efficient and minimal systems [76.158].

Thompson [76.157] used artificial evolution to design an onboard hardware controller for a two-wheeled autonomous mobile robot engaged in simple wall-avoidance behavior in an empty arena. Starting from a random orientation, and position near the wall, the robot had to move to the center of the arena and stay

there using limited sensory input (Fig. 76.29). The direct current (DC) motors driving the wheels were not allowed to run in reverse and the robot's only sensors were a pair of time-of-flight sonars rigidly mounted on the robot, pointing left and right.

Thompson's approach made use of a so-called dynamic state machine (DSM) – a kind of generalized read-only memory (ROM) implementation of a finite-state machine where the usual constraint of strict synchronization of input signals and state transitions are relaxed (in fact put under evolutionary control). The system had access to a global clock whose frequency was also under genetic control. Thus evolution determined whether each signal was synchronized to the clock or allowed to flow asynchronously. This allowed the evolving DSM to be tightly coupled to the dynamics of interaction between the robot and environment and for evolution to explore a wide range of systems dynamics. The process took place within the robot in a kind of *virtual reality* in the sense that the real evolving hardware controlled the real motors, but the wheels were just spinning in the air. The movements that the robot would have actually performed if the wheels had been supporting it were then simulated and the sonar echo signals that the robot was expected to receive were supplied in real time to the hardware DSM. Excellent performance was attained after 35 generations, with good transfer from the virtual environment to the real world (Fig. 76.29).

Shortly after this research was performed, particular types of field programmable gate arrays (FPGAs) which were appropriate for evolutionary applications became available. FPGAs are reconfigurable systems allowing the construction of circuits built from basic logic elements. Thompson exploited their properties to demonstrate evolution directly in the chip. By again relaxing standard constraints, such as synchronizing all elements with a central clock, he was able to develop very novel forms of functional circuits, including a controller for a Khepera robot using infrared sensors to avoid obstacles [76.158, 159].

Following Thompson's pioneering work, *Keymeulen* et al. evolved a robot control system using a Boolean function approach implemented on gate-level evolvable hardware [76.160]. This system acted as a navigation system for a mobile robot capable of locating and reaching a colored ball while avoiding obstacles. The robot was equipped with infrared sensors and an vision system giving the direction and distance to the target. A programmable logic device (PLD) was

Fig.76.29a–d Wall-avoidance behavior of a robot with an evolved hardware controller in virtual reality (a–c) and the real world (d)

used to implement a Boolean function in its disjunctive form. This work demonstrated that such gate-level evolvable hardware was able to take advantage of the correlations in the input states and to exhibit useful generalization abilities, thus allowing the evolution of robust behavior in simulation followed by a good transfer into the real world.

In a rather different approach, *Ritter et al.* used an FPGA implementation of an onboard evolutionary algorithm to develop a controller for a hexapod

robot [76.161]. *Roggen et al.* devised a multicellular reconfigurable circuit capable of evolution, self-repair, and adaptation [76.162], and used it as a substrate for evolving spiking controllers of a wheeled robot [76.163]. Although evolved hardware controllers are not widely used in evolutionary robotics, they still hold out the promise of some very useful properties, such as robustness to faults, which make them interesting for extreme condition applications such as space robotics.

76.11 Closing Remarks

Evolutionary robotics is a young and integrated approach to robot development without human intervention where machines change and adapt by capitalizing on the interactions with their environment. Despite initial skepticism by mainstream and applied robotics practitioners and even by pioneers of this approach [76.164], over the years the field has been constantly growing with new methods and approaches for evolving more complex, efficient, and sometimes surprising robotic systems. In some areas, such as morphology and self-assembly, evolutionary robotics is still the most widely used and powerful approach.

Evolutionary robotics is not only a method for automatic robot development inspired by biology, but

also a tool for investigating open questions in biology concerning evolutionary, developmental, and brain dynamics. Its richness and fecundity make us believe that this approach will continue to grow and progress towards the creation of a new species of machines capable of self-evolution.

To gain a practical knowledge, interested readers might use software libraries such as framework for autonomous robotics simulation and analysis (*FARSA*) [76.165], an open-software tool that permit to carry on evolutionary robotics experiments based on a variety of robotic platforms and to replicate and vary some of the experiments described in this chapter [76.166].

77. Neurorobotics: From Vision to Action

Patrick van der Smagt, Michael A. Arbib, Giorgio Metta

The lay view of a robot is a mechanical human, and thus robotics has always been inspired by attempts to emulate biology. In this chapter, we extend this biological motivation from humans to animals more generally, but with a focus on the central nervous systems in its relationship to the bodies of these creatures. In particular, we investigate the sensorimotor loop in the execution of sophisticated behavior. Some of these sections concentrate on cases where vision provides key sensory data. Neuroethology is the study of the brain mechanisms underlying animal behavior, and Sect. 77.2 exemplifies the lessons it has to offer robotics by looking at optic flow in bees, visually guided behavior in frogs, and navigation in rats, turning then to the coordination of behaviors and the role of attention. Brains are composed of diverse subsystems, many of which are relevant to robotics, but we have chosen just two regions of the mammalian brain for detailed analysis. Section 77.3 presents the cerebellum. While we can plan and execute actions without a cerebellum, the actions are no longer graceful and become uncoordinated. We reveal how a cerebellum can provide a key ingredient in an adaptive control system, tuning parameters both within and between motor schemas. Section 77.4 turns to the mirror system, which provides shared representations which bridge between the execution of an action and the observation of that action when performed by others. We develop a neurobiological model of how learning may forge mirror neurons for hand movements, provide a Bayesian view of

a robot mirror system, and discuss what must be added to a mirror system to support robot imitation. We conclude by emphasizing that, while neuroscience can inspire novel robotic designs, it is also the case that robots can be used as embodied test beds for the analysis of brain models.

77.1 Definitions and History

Neurorobotics may be defined as:

the design of computational structures for robots inspired by the study of the nervous systems of humans and other animals.

We note the success of (deep) *artificial* neural networks – networks of simple computing elements whose connections change with *experience* – as providing a medium for parallel adaptive computation that has seen application in robot vision systems and controllers but here we emphasize neural networks derived from the study of specific *neurobiological* systems. Neuro-robotics has a twofold aim: creating better machines which employ the principles of natural neural computation; and using the study of bio-inspired robots to improve understanding of the functioning of the brain. Chapter 75, *Biologically Inspired Robots*, complements our study of *brain design* with work on *body design*, the design of robotic control and actuator systems based on careful study of the relevant biology.

77.1.1 History and Definitions

Science has long been playing with technical replicas of biological behavior. As a famous example, *Walter* [77.1] described two *biologically inspired* robots, the electromechanical tortoises *Machina speculatrix* and *M. docilis* (though each body has wheels, not legs). *M. speculatrix* has a steerable photoelectric cell, which makes it sensitive to light, and an electrical contact, which allows it to respond when it bumps into obstacles. The photoreceptor rotates until a light of moderate intensity is registered, at which time the organism orients itself towards the light and approaches it. However, very bright lights, material obstacles, and steep gradients are repellent to the *tortoise*. The latter stimuli convert the photoamplifier into an oscillator, which causes alternating movements of butting and withdrawal, so that the robot pushes small objects out of its way, goes around heavy ones, and avoids slopes. The *tortoise* has a *hutch*, which contains a bright light. When the machine's batteries are charged, this bright light is repellent. When the batteries are low, the light becomes attractive to the machine and the light continues to exert an attraction until the tortoise enters the hutch, where the machine's circuitry is temporarily turned off until the batteries are recharged, at which time the bright hutch light again exerts a negative tropism. The second robot, *M. docilis* was produced by grafting onto *M. speculatrix* a circuit designed to

form conditioned reflexes. In one experiment, Walter connected this circuit to the obstacle-avoiding device in *M. speculatrix*. Training consisted of blowing a whistle just before bumping the shell.

Although Walter's controllers are simple and not based on neural analysis, they do illustrate an attempt to gain inspiration from seeking the simplest mechanisms that will yield an interesting class of biologically inspired robot behaviors, and then showing how different additional mechanisms yield a variety of enriched behaviors. *Braitenberg's* book [77.2] is very much in this spirit and has entered the canon of neurorobotics. While their work provides a historical background for the studies surveyed here, we instead emphasize studies inspired by the computational neuroscience of the mechanisms serving vision and action in the human and in animal brains. We seek lessons from linking behavior to the analysis of the internal workings of the brain (1) at the relatively high level of characterizing the functional roles of specific brain regions (or the functional units of analysis called schemas, Sect. 77.2.4), and the behaviors which emerge from the interactions between them, and (2) at the more detailed level of models of neural circuitry linked to the data of neuroanatomy and neurophysiology. There are lessons for neurorobotics to be learned from even finer-scale analysis of the biophysics of individual neurons and the neurochemistry of synaptic plasticity, but these are beyond the scope of this chapter (see *Segev and London* [77.3] and *Fregnac* [77.4], respectively, for entry points into the relevant computational neuroscience).

The plan of this chapter is as follows. We will start with explaining how the higher-level *cognitive* functionality of vision-based planning and navigation is realized in biology, and how this relates to robotic systems (Sect. 77.2). We then (Sect. 77.3) explain vertebrate movement generation itself, and put forth a theory on what role the cerebellum plays in tuning and coordinating actions. This is followed by a section on the mirror system and its roles in action recognition and imitation (Sect. 77.4). The introduction will then invite readers to explore the many other areas in which neurorobotics offers lessons from neuroscience to the development of novel robot designs. What follows, then, can be seen as a contribution to the continuing dialog between robot behavior and animal and human behavior in which particular emphasis is placed on the search for the neural underpinnings of vision, visually guided action, and cerebellar control.

77.2 The Case for Vision

Before we turn to vertebrate brains for much of our inspiration for neurobotics, we briefly sample the rich literature on insect-inspired research. Among the founding studies in computational neuroethology were a series of reports from the laboratory of Werner Reichardt in Tübingen, which linked the delicate anatomy of the fly's brain to the extraction of visual data needed for flight control. More than 40 years ago, Reichardt [77.5] published a model of motion detection inspired by this work that has long been central to discussions of visual motion in both the neuroscience and robotics literatures. Borst and Dickinson [77.6] provide a recent study of continuing biological research on visual course control in flies. Such work has inspired a large number of robot studies, including those of van der Smagt and Groen [77.7], van der Smagt [77.8], Liu and Usseglio-Viretta [77.9], Ruffier et al. [77.10], and Reiser and Dickinson [77.11].

77.2.1 Optic Flow in Bees and Robots

Here, however, we look in a little more detail at honeybees. Srinivasan et al. [77.15] continued the tradition of studying image motion cues in insects by investigating how optic flow (the flow of pattern across the eye induced by motion relative to the environment) is exploited by honeybees to guide locomotion and navigation. They analyzed how bees perform a smooth

Fig. 77.1 (a) Observation of the trajectories of honeybees flying in visually textured tunnels has provided insights into how bees use optic flow cues to regulate flight speed and estimate distance flown, and balance optic flow in the two eyes to fly safely through narrow gaps (images courtesy of Srinivasan et al. [77.12]). This information has been used to build autonomously navigating robots. (b) Schematic illustration of a honeybee brain, carrying about a million neurons within $\approx 1 \text{ mm}^3$ (after [77.13]). (c) A mobile robot guided by an optic flow algorithm based on the studies exemplified in [77.14]

landing on a flat surface: image velocity is held constant as the surface is approached, thus automatically ensuring that flight speed is close to zero at touchdown. This obviates any need for explicit knowledge of flight speed or height above the *ground*. This landing strategy was then implemented in a robotic gantry to test its applicability to autonomous airborne vehicles. Barron and Srinivasan [77.14] investigated the extent to which ground speed is affected by headwinds. Honeybees were trained to enter a tunnel to forage at a sucrose feeder placed at its far end (Fig. 77.1a). The bees used visual cues to maintain their ground speed by adjusting their airspeed to maintain a constant rate of optic flow, even against headwinds which were, at their strongest, 50% of a bee's maximum recorded forward velocity.

Vladusich et al. [77.16] studied the effect of adding goal-defining landmarks. Bees were trained to forage in an optic-flow-rich tunnel with a landmark positioned directly above the feeder. They searched much more accurately when both odometric and landmark cues were available than when only odometry was available. When the two cue sources were set in conflict, by shifting the position of the landmark in the tunnel during tests, bees overwhelmingly used landmark cues rather than odometry. This, together with other such experiments, suggests that bees can make use of odometric and landmark cues in a more flexible and dynamic way than previously envisaged. In earlier studies of bees flying down a tunnel, Srinivasan and Zhang [77.17] placed different patterns on the left and right walls. They found that bees balance the image velocities in the left and right visual fields. This strategy ensures that bees fly down the middle of the tunnel, without bumping into the side walls, enabling them to negotiate narrow passages or to fly between obstacles. This strategy has been applied to a corridor-following robot (Fig. 77.1c). By holding constant the average image velocity as seen by the two eyes during flight, the bee avoids potential collisions, slowing down when it flies through a narrow passage. The movement-sensitive mechanisms underlying these various behaviors differ qualitatively as well as quantitatively, from those that mediate the optomotor response (e.g., turning to track a pattern of moving stripes) that had been the initial target of investigation of the Reichardt laboratory. The lesson for robot control is that flight appears to be coordinated by a number of visuomotor systems acting in concert, and the same lesson can apply to a whole range of tasks that must convert vision to action. Of *course*, vision is but one of the sensory systems that play a vital role in insect behavior. Webb [77.18] uses her own work on robot

design inspired by the auditory control of behavior in crickets to anchor a far-ranging assessment of the extent to which robotics can offer good models of animal behaviors.

77.2.2 Visually Guided Behavior in Frogs and Robots

Lettvin et al. [77.19] treated the frog's visual system from an ethological perspective, analyzing circuitry in relation to the animal's ecological niche to show that different cells in the retina and the visual midbrain region known as the tectum were specialized for detecting predators and prey. However, in much visually guided behavior, the animal does not respond to a single stimulus, but rather to some property of the overall configuration. We thus turn to the question *what does the frog's eye tell the frog?*, stressing the embodied nervous system or, perhaps equivalently, an action-oriented view of perception. Consider, for example, the snapping behavior of frogs confronted with one or more fly-like stimuli. Ingle [77.20] found that it is only in a restricted region around the head of a frog that the presence of a fly-like stimulus elicits a snap, that is, the frog turns so that its midline is pointed at the stimulus and then lunges forward and captures the prey with its tongue. There is a larger zone in which the frog merely orients towards the target, and beyond that zone the stimulus elicits no response at all. When confronted with two flies within the snapping zone, either of which is vigorous enough that it could elicit a snapping response alone, the frog exhibits one of three reactions: it snaps at one of the flies, it does not snap at all, or it snaps in between at the *average fly*. Didday [77.21] offered a simple model of this choice behavior which may be considered as the prototype for a *winner-take-all* (WTA) model, which receives a variety of inputs and (under ideal circumstances) suppresses the representation of all but one of them; the one that remains is the *winner* that will play the decisive role in further processing. This was the beginning of *Rana computatrix* (see Arbib [77.22, 23] for overviews).

Studies on frog brains and behavior inspired the successful use of potential fields for robot navigation strategies. Data on the strategies used by frogs to capture prey while avoiding static obstacles (Collett [77.24]) grounded the model by Arbib and House [77.25], which linked systems for depth perception to the creation of spatial maps of both prey and barriers. In one version of their model, they represented the map of prey by a potential field with long-range attraction and the map of barriers by a potential field with short-range repulsion, and showed that summation of these fields yielded a field that could guide the frog's de-

tour around the barrier to catch its prey. Corbacho and Arbib [77.26] later explored a possible role for learning in this behavior. Their model incorporated learning in the weights between the various potential fields to enable adaptation over trials as observed in the real animals. The success of the models indicated that frogs use reactive strategies to avoid obstacles while moving to a goal, rather than employing a planning or cognitive system. Other work, Cobas and Arbib [77.27], studied how the frog's ability to catch prey and avoid obstacles was integrated with its ability to escape from predators. These models stressed the interaction of the tectum with a variety of other brain regions such as the pretectum (for detecting predators) and the tegmentum (for implementing motor commands for approach or avoidance).

Arkin [77.28] showed how to combine a computer vision system with a frog-inspired potential field controller to create a control system for a mobile robot that *could* successfully navigate in a fairly structured environment using camera input. The resultant system thus enriched other roughly contemporaneous applications of potential fields in path planning with obstacle avoidance for both manipulators and mobile robots (Khatib [77.29], Krogh and Thorpe [77.30]). The work on *Rana computatrix* proceeded at two levels – both biologically realistic neural networks and in terms of functional units called *schemas*, which compete and cooperate to determine behavior. Section 77.2.4 will show how more general behaviors can emerge from the competition and cooperation of perceptual and motor schemas, as well as more abstract coordinating schemas. Such ideas were, of course, developed independently by a number of authors, and so entered the robotics literature by various routes, of which the best known may be the subsumption architecture of Brooks [77.31] and the ideas of Braitenberg cited above, whereas Arkin's work on behavior-based robotics [77.32] is, indeed, rooted in schema theory. Arkin et al. [77.33] present a recent example of the continuing interaction between robotics and ethology, offering a novel method for creating high-fidelity models of animal behavior for use in robotic systems based on a behavioral systems approach (i. e., based on a schema-level model of animal behavior, rather than analysis of biological circuits in animal brains), and describe how an ethological model of a domestic dog can be implemented with AIBO, the Sony entertainment robot.

77.2.3 Navigation in Rat and Robot

The tectum, the midbrain visual system which determines how the frog turns its whole body towards its prey or orients it for escape from predators (Sect. 77.2.2), is

homologous with the superior colliculus of the mammalian midbrain. The rat superior colliculus has been shown to be *frog like*, mediating approach and avoidance (Dean et al. [77.34]), whereas the best-studied role of the superior colliculus of cat, monkey, and human is in the control of saccades, rapid eye movements to acquire a visual target. Moreover, the superior colliculus can integrate auditory and somatosensory information into its visual frame (Stein and Meredith [77.35]), and this inspired Strosslin et al. [77.36] to use a biologically inspired approach based on the properties of neurons in the superior colliculus to learn the relation between visual and tactile information in control of a mobile robot platform. More generally, then, the comparative study of mammalian brains has yielded a rich variety of computational models of importance in neurobotics. In this section, we further introduce the study of *mammalian neurobotics* by looking at studies of mechanisms of the rat brain for spatial navigation.

The frog's detour behavior is an example of what O'Keefe and Nadel [77.37] called the *taxon* (*behavioral orientation*) system (as in Braitenberg, [77.38] a *taxis* (plural *taxes*) is an organism's response to a stimulus by movement in a particular direction). They distinguished this from a system for *map-based navigation* and proposed that the latter resides in the hippocampus, though Guazzelli et al. [77.39] qualified this assertion, showing how the hippocampus may function as *part of* a cognitive map. The *taxon* versus *map* distinction is akin to the distinction between reactive and deliberative control in robotics (Arkin et al. [77.33]). It will be useful to relate *taxis* to the notion of an *affordance* (Gibson [77.40]), a feature of an object or environment relevant to action, for example, in picking up an apple or a ball, the identity of the object may be irrelevant, but the size of the object is crucial. Similarly, if we wish to push a toy car, recognizing the make of car copied in the toy is irrelevant, whereas it is crucial to recognize the placement of the wheels to extract the direction in which the car can be readily pushed. Just as a rat may have basic *taxes* for approaching food or avoiding a bright light, say, so does it have a wider repertoire of affordances for possible actions associated with the immediate sensing of its environment. Such affordances include *go straight ahead* for visual sighting of a corridor, *hide* for a dark hole, *eat* for food as sensed generically, *drink* similarly, and the various turns afforded by, e.g., the sight of the end of the corridor. It also makes rich use of olfactory cues. In the same way, a robot's behavior will rely on a host of reactions to local conditions in fulfilling a plan, e.g., knowing that it must go to the end of a corridor it will nonetheless use local visual cues to avoid hitting obstacles or to determine through which angle to turn when reaching a bend in the corridor.

Both normal and hippocampal-lesioned rats can learn to solve a simple T-maze (e.g., learning whether to turn left or right to find food) in the absence of any consistent environmental cues other than the T-shape of the maze. If anything, the lesioned animals learn this problem faster than normal ones. After the criterion was reached, probe trials with an eight-arm radial maze were interspersed with the usual T-trials. Animals from both groups consistently chose the side to which they were trained on the T-maze. However, many did not choose the 90° arm but preferred either the 45° or 135° arm, suggesting that the rats eventually solved the T-maze by learning to rotate within an ego-centric orientation system at the choice point through *approximately* 90°. This leads to the hypothesis of an *orientation vector* being stored in the animal's brain but does not tell us where or how the orientation vector is stored. One possible model would employ coarse coding in a linear array of cells, coding for turns from -180° to +180°. From the behavior, one might expect that only the cells close to the preferred *behavioral* direction are excited, and that learning *marches* this peak from the old to the new preferred direction. To *unlearn* -90°, say, the array must reduce the peak there, while at the same time *building* a new peak at the new direction of +90°. If the old peak has *massp(t)* and the new peak has *massq(t)*, then as *p(t)* declines toward 0 while *q(t)* increases steadily from 0, the center of mass will progress from -90° to +90°, fitting the behavioral data.

The determination of movement direction was modeled by *rat-ification* of the *Arbib* and *House* [77.25] model of frog detour behavior. There, prey was represented by excitation coarsely coded across a population, while barriers were encoded by inhibition whose extent closely matched the retinotopic extent of each barrier. The sum of excitation was passed through a winner-takes-all circuit to yield the choice of movement direction. As a result, the direction of the gap closest to the prey, rather than the direction of the prey itself, was often chosen for the frog's initial movement. The same model serves for behavioral orientation once we replace the direction of the prey (frog) by the direction of the orientation vector (rat), while the barriers correspond to the presence of walls rather than alley ways.

To approach the issue of how a cognitive map can extend the capability of the affordance system, Guazzelli et al. [77.39] extended the *Lieblisch* and *Arbib* [77.41] approach to building a cognitive map as a *world graph*, a set of nodes connected by a set of edges, where the nodes represent recognized places or situations, and the links represent ways of moving from one situation to another. A crucial notion is that a place encountered in different circumstances may be repre-

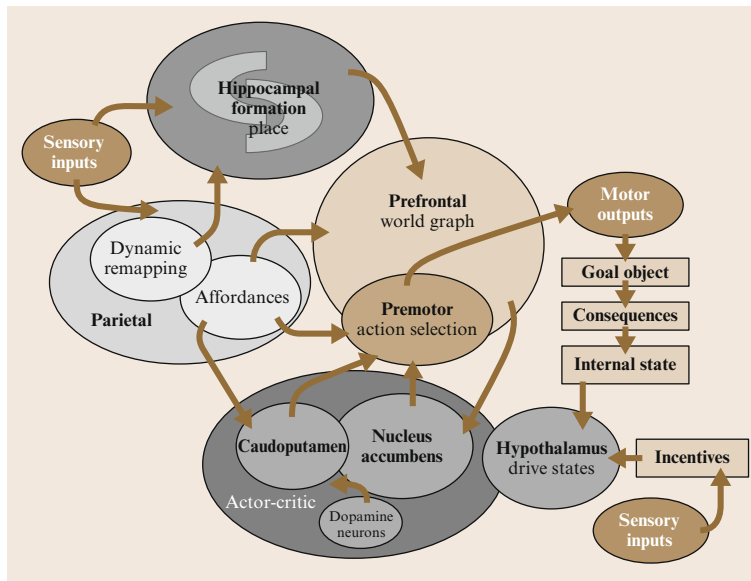

Fig. 77.2 The TAM-WG model has at its basis a system, TAM (the taxon affordance model), for exploiting affordances. This is elaborated by a system, WG (the world graph), which can use a cognitive map to plan paths to targets which are not currently visible. Note that the model processes two different kinds of sensory inputs. At the *bottom right* are those associated with, e.g., hypothalamic systems for feeding and drinking and that may provide both incentives and rewards for the animal's behavior, contributing both to behavioral choices, and to the reinforcement of certain patterns of behavior. The nucleus accumbens and caudoputamen mediate an actor-critic style of reinforcement learning based on the hypothalamic drive of the dopamine system. The sensory inputs at the *top left* are those that allow the animal to sense its relation with the external world, determining both where it is (the hippocampal place system), as well as the affordances for action (the parietal recognition of affordances can shape the premotor selection of an action). The TAM model focuses on the parietal–premotor reaction to immediate affordances; the WG model places action selection within the wider context of a cognitive map (after Guazzelli et al. [77.39])

sented by multiple nodes, but that these nodes may be merged when the similarity between these circumstances is recognized. They model the process whereby the animal decides where to move next, on the basis of its current drive state (hunger, thirst, fear, etc.). The emphasis is on spatial maps for guiding locomotion into regions not necessarily currently visible, rather than retinotopic representations of immediately visible space, and yields exploration and latent learning without the introduction of an explicit exploratory drive. The model shows:

1. How a route, possibly of many steps, may be chosen that leads to the desired goal.
2. How short cuts may be chosen.
3. Through its account of node merging why, in open fields, place cell firing does not seem to depend on direction.

The overall structure and general mode of operation of the complete model is shown in Fig. 77.2, which gives a vivid sense of the lessons to be learned by studying not only specific systems of the mammalian brain

but also their patterns of large-scale interaction. This model is but one of many inspired by the data on the role of the hippocampus and other regions in rat navigation. Here, we just mention as pointers the wider literature the papers by Girard et al. [77.42] and Meyer et al. [77.43], which are part of the *Psikharpax* project, which does for rats what *Rana computatrix* did for frogs and toads.

77.2.4 Saliency and Visual Attention

Discussions of how an animal (or robot) grasps an object assume that the animal or robot is attending to the relevant object. Thus, whatever the subtlety of processing in the canonical and mirror systems for grasping, its success rests on the availability of a visual system coupled to an oculomotor control system that bring foveal vision to bear on objects to set the parameters needed for successful interaction. Indeed, the general point is that attention greatly reduces the processing load for animal and robot. The catch, of course, is that reducing the computing load is a Pyrrhic victory unless

the moving focus of attention captures those aspects of behavior that are relevant for the current task – or supports necessary *priority interrupts*. Indeed, directing attention appropriately is a topic for which there is a great richness of both neurophysiological data and robotic application (see *Deco* and *Rolls* [77.44] and *Choi* et al. [77.45]).

In their neuromorphic model of the bottom-up guidance of attention in primates, *Itti* and *Koch* [77.46] decompose the input video stream into eight feature channels at six spatial scales. After surround suppression, only a sparse number of locations remain active in each map, and all maps are combined into a unique *saliency map*. This map is scanned by the focus of attention in order of decreasing saliency through the interaction between a winner-takes-all mechanism (which selects the most salient location) and an *inhibition-of-return* mechanism (which transiently suppresses recently attended locations from the saliency map). Because it includes a detailed low-level vision front-end, the model has been applied not only to laboratory stimuli, but also to a wide variety of natural scenes, predicting a wealth of data from psychophysical experiments.

When specific objects are searched for, low-level visual processing can be biased both by the gist (e.g., *outdoor suburban scene*) and also for the features of that object. This top-down modulation of bottom-up processing results in an ability to guide search towards targets of interest (*Wolfe* [77.47]). Task affects eye movements (*Yarbus* [77.48]), as do training and general expertise. *Navalpakkam* and *Itti* [77.49] propose a computational model which emphasizes four aspects that are important in biological vision: determining the task relevance of an entity, biasing attention for the low-level visual features of desired targets, recognizing these targets using the same low-level features, and incrementally building a visual map of task relevance

at every scene location. It attends to the most salient location in the scene, and attempts to recognize the attended object through hierarchical matching against object representations stored in long-term memory. It updates its working memory with the task relevance of the recognized entity and updates a topographic task-relevance map with the location and relevance of the recognized entity; for example, in one task the model forms a map of likely locations of cars from a video clip filmed while driving on a highway. Such work illustrates the continuing interaction between models based on visual neurophysiology and human psychophysics with the tackling of practical robotic applications.

Orabona et al. [77.50] implemented an extension of the Itti–Koch model on a humanoid robot with moving eyes, using log-polar vision as in *Sandini* and *Tagliasco* [77.51], and changing the feature construction pyramid by considering proto-object elements (blob-like structures rather than edges). The inhibition-of-return mechanism has to take into account a moving frame of reference, the resolution of the fovea is very different from that at the periphery of the visual field, and head and body movements need to be stabilized. The control of movement might thus have a relationship with the structure and development of the attention system. *Rizzolatti* et al. [77.52] proposed a role for the feedback projections from premotor cortex to the parietal lobe, assuming that they form a tuning signal that dynamically changes visual perception. In practice, this can be seen as an implicit attention system that *selects* sensory information while the action is being prepared and subsequently executed (*Flanagan* and *Johansson* [77.53], *Flanagan* et al. [77.54], and *Mataric* and *Pomplun* [77.55]). The early responses, before action onset, of many premotor and parietal neurons suggest a premotor mechanism of attention that deserves exploration in further work in neurorobotics.

77.3 Vertebrate Motor Control

The body of literature on primate motor control is, of course, vast, and gives a patchy view on the principles behind it. Getting a clear view of how limb and general body control functions is difficult; moreover, there are no clear proofs of whether any of the existing views on motor control are correct.

But there exist a few observations of the human central and peripheral nervous systems from which clear conclusions can be drawn. The first observation is the presence of neural communication delays. How does the system know the position of limbs? There are two principled methods: (1) through proprioceptive signals, consisting of muscle spindles and Golgi tendon or-

gans (GOs); and (2) through skin information. It is, however, not very likely that information from muscle spindles and GOs are accurate enough to code limb position. Tendon organs are sensitive to forces along in-series motor units and there is no physiological evidence that Golgi tendon organs signal muscle length (but, of course, force changes with muscle length, so during movement a correlation is found). There is another problem with respect to limb position, which is particularly clear for fingers: flexibilities and nonlinear relationships between finger position and muscle force, in combination with the imprecise receptors, makes the relationship between GO/spindle data and finger posi-

Table 77.1 Classification of sensory fibers from muscle (after [77.56])

Type	Receptor	Axon diameter [μm]	Transmission speed [m/s]	Sensitive to
Ia	Primary spindle endings	12–20	60–100	Muscle length and rate of change
Ib	Golgi tendon organs	12–20	60–100	Muscle tension
II	Secondary spindle endings	6–12	30–70	Muscle length
III	Free nerve endings	2–6	10–30	Skin signals

tion too complex and variable to be a likely candidate to code finger position; after all, the sensors are in the forearm rather than in the fingers; and information on finger position is not available in muscle movement or tendon force. Furthermore, muscle spindle data is noisy [77.57]. It has conversely been shown [77.58, 59] that the receptors in hairy skin code information that can be related to finger position; furthermore, similar data have been found for the knee joint [77.60]. Table 77.1 lists nerve transmission speeds for these signals.

Since neurons are only to be found in the spinal cord and the brain, for hand skin, therefore, we can expect signal transfer delays to the spine of around 30–100 ms. Round-trip muscle activation is, therefore, around 70 ms for signals based on skin data [77.61], or around 25 ms for spindle-based signals (we have verified these delays by measuring hand skin-based reflexes by measuring the corresponding electromyography(EMG) signals, and found a round-trip delay of around 75 ms. Spindle-based feedback for the wrist was measured at around 25 ms.

Of course, when a sensory signal has to be processed in the brain, the delays are correspondingly longer. At any rate: error-correcting feedback control has delays of several tens of milliseconds; feedback control based on such delays cannot lead to any acceptable accuracy with the movement speeds that humans typically display. This means that large portions of our movement, over time frames in the order of 100 ms or more, need to be controlled open loop.

A second important observation is our generalizing capabilities. Consider the case of playing fast and accurate sports, e.g., table tennis. During play, we obtain sensory visual, haptic, and tactile sensory data, the result of which must lead to an accurate movement of the bat in order to score a point. Even a player with little training is able to do this rather accurately: at ball flight times between 200 and 500 ms, the brain does not have much time to plan an accurate whole-body movement for each and every possible sensory state, but we are usually capable of returning the ball. Training helps, but we do not need to exhaustively learn many states in the very high-dimensional sensor space in which our observations move.

Generalization can only be done with reasonably accurate models of the sensor/motor behavior. How-

ever, models of our motor system are difficult to obtain: variations such as including payloads, wearing heavy clothing, muscle fatigue, etc., do not influence our accuracy considerably.

77.3.1 The Flat Hierarchy of Neurocontrol

How is an open-loop movement generated? In this paper we concentrate on voluntary vertebrate motor control; the only reason for any animal to have a brain is to generate movement. Moreover, despite differences in brain structures, there is a large correspondence in movement patterns among the whole animal kingdom, irrespective of the presence of a cortical structure or a cerebellum. What parts of the brain are directly involved in movement?

The major role of the cerebral cortex seems to be unsupervised learning to establish relationships between sensory and action patterns [77.62]. The neocortex is only to be found in mammals; experiments with decorticated cats [77.63] clearly show that the cortex is not necessary to generate movement; rather, it is likely that the motor cortex models and weighs movements, to subsequently make decisions based thereon.

The major role of the basal ganglia seems to be reinforcement learning to filter out unwanted movements [77.62]. They play a dominant role in movement generation or gating (filtering) of generated movement patterns. The effect of Parkinson’s disease (the inability to initiate movement) and Huntington’s disease (the inability to prevent unwanted movement) on the basal ganglia is well known and clearly indicates their function.

The major role of the cerebellum seems to be supervised learning of motor patterns [77.62]. Moreover, decerebellation does not lead to complete movement loss. An individual with cerebellar lesions may be able to move the arm to successfully reach a target and to successfully adjust the hand to the size of an object. However, the action cannot be made swiftly and accurately, and the ability to coordinate the timing of the two subactions is lacking. The behavior will thus exhibit decomposition of movement – first the hand is moved until the thumb touches the object, and only then is the hand shaped appropriately to grasp the object [77.64].

Robot control usually favors a strict hierarchical approach. A typical robot works as follows. At the low-

est level, a very fast ($\approx 100 \mu\text{s}$) current control loop controls the rotation of the dc motor. On top of that, a torque controller (running typically at 1 kHz) controls the torque of all joints, and is in its turn controlled by an impedance or position controller. On top of that, typically, a Cartesian path planner forms the slowest loop. An error in any of these elements will disable the robot.

A look into evolutionary development of neural control thus makes immediately clear that a strict hierarchical approach is not viable in neural control. Although any of the above-mentioned brain regions is important in movement control, and similar structures can be found in any vertebrate, their dysfunction leads to movement degradation but not to movement loss (this is, of course, not true for the spinal cord, which (combines and) transmits the controls to the muscles). Also, the development of the neural system shows that animals were always capable of movement – irrespective of their brain structure. However, the cerebellum is usually rightly focused upon when analyzing vertebrate movement. How do the parts of the brain collaborate towards smooth goal-directed movement?

In placing the function of the cerebellum in the loop, a normal distinction is to consider the cerebellum as representing (a) a forward or direct model which represents the path from motor command to motor output, or (b) an inverse model of motor function, i.e., going from a desired motor outcome to a set of motor commands likely to achieve it. As we have just suggested, the action plan unfolds as if it were feedforward or open loop when the actual parameters of the situation match the stored parameters, while a feedback component is employed to counteract disturbances (current feedback) and to learn from mistakes (learning from feedback). This is obtained by relying on a forward model that predicts the outcome of the action as it unfolds in real time. The accuracy of the forward model can be evaluated by comparing the output generated by the system with the signals derived from sensory feedback (Miall et al. [77.65]). Also, delays must be accounted for to address the different propagation times of the neural pathways carrying the predicted and actual outcome of the action. Note that the forward model in this case is relatively simple, predicting only the motor output in advance; since motor commands are generated internally it is easy to imagine a predictor for these signals (known as an efference copy). The inverse model, on the other hand, is much more complicated since it maps sensory feedback (e.g., vision) back into motor terms.

We suggest a much simpler approach to the vertebrate control system. However, let us first look into the functionality of the lower-level apparatus: muscle, spinal cord, and cerebellum.

77.3.2 On Spinal Cord and Muscle

The key element in movement generation is given by two building blocks: (a) our muscles, and (b) the spinal cord. Muscle behavior is strongly nonlinear; the exerted force decreases nonlinearly with velocity (Fig. 77.3) and varies nonlinearly with length (Fig. 77.4).

Limb movement, however, is caused by a complex of muscles – for instance, the human arm uses a total of 19 muscle groups for planar motion of the elbow and shoulder alone (Nijhof and Kouwenhoven [77.67]) with altogether highly nonlinear dynamics. How can this large number of actuators be controlled without feedback error control?

The concept is simple and was first well described by Bernstein [77.68]: skeletal muscles are always controlled in functional groups, leading to *synergies* of movement. Rather than activating muscles indepen-

Fig. 77.3 The force/velocity and power/velocity relationship of muscle (after [77.56])

Fig. 77.4 The force/length relationship of muscle (after [77.56])

Fig. 77.5 (a) Major cells in the cerebellum. (b) Cells in the Marr–Albus model. The granule cells are state encoders, feeding system state, and sensor data into the PC. PC/PF synapses are adjusted using the Widrow–Hoff rule. The output of the PC are steering signals for the robotic system. (c) The APG model, using the same state encoder as in (b). (d) The MPFIM model. A single module corresponds to a group of Purkinje cells: predictor, controller, and responsibility estimator. The granule cells generate the necessary basis functions of the original information (after [77.66])

dently, a neural signal controls groups of muscles that perform (a part of) an action. Linear dimension reduction methods [77.69] (e.g., principal component analysis, (PCA), independent component analysis (ICA), or non-negative matrix factorization (NMF)) have been used to establish synergies in EMG data, and this can be used [77.70] to linearly combine single-finger movement to whole-hand movement in EMG space. So, we cannot control single muscles (i.e., coherent groups of muscle fibers) but rather control muscle groups, the linear combination of which can be used to span a decent part of our voluntary movement.

There are currently still open questions as to the nature of movement synergies: how much of the synergies are defined by the biomechanical structure of our muscles and tendons; how much of it is laid out in the spinal cord; and which part of it is learned in the higher movement control regions?

77.3.3 Models of Cerebellar Control

The cerebellum can be divided into two parts: the cortex and the deep nuclei. There are two systems of fibers bringing input to the both the cortex and nuclei: the mossy fibers and the climbing fibers. The only output

from the cerebellar nucleus comes from cells called Purkinje cells, and they project only to the cerebellar nuclei, where their effect is inhibitory. This inhibition sculpts the output of the nuclei which (the effect varies from nucleus to nucleus) may act by modulating activity in the spinal cord, the mid-brain, or the cerebral cortex. We now turn to models that make explicit use of the cellular structure of the cerebellar cortex (see Eccles et al. [77.71] and Ito [77.72], and also Fig. 77.5a). The human cerebellum has 7–14 million Purkinje cells (PCs), each receiving about 200 000 synapses. Mossy fibers (MFs) arise from the spinal cord and brainstem. They synapse onto granule cells and deep cerebellar nuclei. Granule cells have axons which each project up to form a T, with the bars of the T forming the parallel fibers (PFs). Each PF synapses on about 200 PCs. The PCs, which are grouped into microzones, inhibit the deep nuclei. PCs with their target cells in cerebellar nuclei are grouped together in microcomplexes [77.72]. Microcomplexes are defined by a variety of criteria to serve as the units of analysis of cerebellar influence on specific types of motor activity. The climbing fibers (CFs) arise from the inferior olive (IO). Each PC receives synapses from only one CF, but a CF makes about 300 excitatory synapses on each PC that it con-

tacts. This powerful input alone is enough to fire the **PC**, though most **PC** firing depends on subtle patterns of **PF** activity. The cerebellar cortex also contains a variety of inhibitory interneurons. The basket cell is activated by **PF** afferents and makes inhibitory synapses onto **PCs**. Golgi cells receive input from **PFs**, **MFs**, and **CFs**, and inhibit granule cells.

The Marr–Albus Model

In the Marr–Albus model (Marr [77.73] and Albus [77.74]) the cerebellum functions as a classifier of sensory and motor patterns received through the **MFs**. Only a small fraction of the parallel fibers (**PF**) are active when a Purkinje cell (**PC**) fires and thus influence the motor neurons. Both Marr and Albus hypothesized that the error signals for improving **PC** firing in response to **PF**, and thus **MF** input were provided by the climbing fibers (**CF**), since only one **CF** affects a given **PC**. However, Marr hypothesized that **CF** activity would strengthen the active **PF/PC** synapses using a Widrow–Hoff learning rule, whereas Albus hypothesized they would weaken them. This is an important example of a case where computational modeling inspired important experimentation. Eventually, Masao Ito was able to demonstrate that Albus was correct – the weakening of active synapses is now known to involve a process called long-term depression [77.72]. However, the rule with weakening of synapses is still known as the Marr–Albus model, and remains the reference model for studies of synaptic plasticity of the cerebellar cortex. However, both Marr and Albus viewed each **PC** as functioning as a perceptron whose job it was to control an elemental movement, contrasting with more plausible models in which **PCs** serve to modulate the involvement of microcomplexes (which include cells of the deep nuclei) in motor pattern generators (e.g., the **APG** model described below).

Since the development of the Marr–Albus model several cerebellar models have been introduced in which cerebellar plasticity plays a key role. Limiting our overview to computational models, we will describe:

1. The **CMAC** (cerebellar model articulation controller).
2. The adjustable pattern generator (**APG**).
3. The Schweighofer–Arbib model.
4. The multiple paired forward-inverse models [77.75, 76].

The Cerebellar Model Articulation Controller

One of the first well-known computational models of the cerebellum is the **CMAC** (Albus [77.77]; Fig. 77.5b). The algorithm was based on Albus' un-

derstanding of the cerebellum, but it was not proposed as a biologically plausible model. The idea has its origins in the BOXES approach, in which for n variables an n -dimensional hypercube stores function values in a lookup table. BOXES suffers from the curse of dimensionality: if each variable can be discretized into D different steps, the hypercube has to store D^n function values in memory. Albus assumed that the mossy fibers provided discretized function values. If the signal on a mossy fiber is in the receptive field of a particular granule cell, it fires onto a parallel fiber. This mapping of inputs onto binary output variables is often considered to be the generalization mechanism in **CMAC**. The learning signals are provided by the climbing fibers.

Albus' **CMAC** can be described in terms of a large set of overlapping, multidimensional receptive fields with finite boundaries. Every input vector falls within the range of some local receptive fields. The response of **CMAC** to a given input is determined by the average of the responses of the receptive fields excited by that input. Similarly, the training for a given input vector affects only the parameters of the excited receptive fields.

The organization of the receptive fields of a typical Albus **CMAC** with a two-dimensional input space can be described as follows. The set of overlapping receptive fields is divided into C subsets, commonly referred to as *layers*. Any input vector excites one receptive field from each layer, for a total of C excited receptive fields for any input. The overlap of the receptive fields produces input generalization, while the offset of the adjacent layers of receptive fields produces input quantization. The ratio of the width of each receptive field (input generalization) to the offset between adjacent layers of receptive fields (input quantization) must be equal to C for all dimensions of the input space. This organization of the receptive fields guarantees that only a fixed number, C , of receptive fields is excited by any input.

If a receptive field is excited, its response equals the magnitude of a single adjustable weight specific to that receptive field. The **CMAC** output is the average of the weights of the excited receptive fields. If nearby points in the input space excite the same receptive fields, they produce the same output value. The output only changes when the input crosses one of the receptive field boundaries. The Albus **CMAC** thus produces piecewise-constant outputs. Learning takes place as described above.

CMAC neural networks have been applied in various control situations Miller [77.78], starting from adaptation of **PID** (proportional–integral–derivative) control parameters for an industrial robot arm and

hand–eye systems up to biped walking (see, for instance, *Sabourin and Bruneau [77.79]*).

The Adjustable Pattern Generator APG

The APG model (*Houk et al. [77.80]*) got its name because the model can generate a burst command with adjustable intensity and duration. The APG is based on the same understanding of the mossy fiber–granule cell–parallel fiber structure as CMAC, using the same state encoder, but has the crucial difference (Fig. 77.2c) that the role of the nuclei is crucial. In the APG model, each nucleus cell is connected to a motor cell in a feedback circuit. Activity in the loop is then modulated by Purkinje cell inhibition, a modeling idea introduced by *Arbib et al. [77.81]*.

The learning algorithm determines which of the PF–PC synapses will be updated in order to improve movement generation performance. This is the traditional credit assignment problem: *which* synapse (the structural credit assignment) must be updated based on a response issued *when* (temporal credit assignment). While the former is solved by the CFs, which are considered binary signals, for the latter eligibility traces on the synapses are introduced, serving as memory for recent activity to determine which synapses are eligible for updates. The motivation for the eligibility signal is this: each firing of a PC cell will take some time to affect the animal’s movement, and a further delay will occur before the CF can signal an error in the movement in which the PC is involved. Thus the error signal should not affect those PF–PC synapses that are currently active, but should instead act upon those synapses that affected the activity whose error is now being registered.

The Schweighofer–Arbib Model

The Schweighofer–Arbib model was introduced in *Schweighofer [77.82]*. It does not use the CMAC state encoder but tries to copy the anatomy of the cerebellum. All the cells, fibers, and axons in Fig. 77.2a are included. Several assumptions are made:

1. There are two types of mossy fibers, one type reflecting the desired state of the controlled plant and another carrying information on the current state. A mossy fiber diverges into approximately 16 branches.
2. Granule cells have an average of four dendrites, each of which receive input from different mossy fibers through a synaptic structure called the glomerulus.
3. Three Golgi cells synapse on a granule cell through the glomerulus and the strength of their influence depends on the simulated geometric distance between the glomerulus and the Golgi cell.

4. The climbing fiber connection on nuclear cells as well as deep nuclei is neglected.

Learning in this model depends on directed error information given by the climbing fibers from the inferior olive (IO). Here, long-term depression is performed when the IO firing rate provides an error signal for an eligible synapse, while compensatory but slower increases in synaptic strength can occur when no error signal is present. Schweighofer applied the model to explain several acknowledged cerebellar system functions:

1. Saccadic eye movements
2. Two-link limb movement control *Schweighofer et al. [77.83, 84]*
3. Prism adaptation (*Arbib et al. [77.85]*).

Furthermore, control of a simulated human arm was demonstrated.

Multiple Paired Forward–Inverse Models (MPFIM)

Building on a long history of cerebellar modeling, *Wolpert and Kawato [77.86]* proposed a functional model of the cerebellum, which uses multiple coupled predictors and controllers that are trained for control, each being responsible for a small state-space region. The MPFIM model is based on the indirect/direct model approach by Kawato, and is also based on the microcomplex theory. We noted earlier that a microzone is a group of PCs, while a microcomplex combines the PCs of a microzone with their target cells in cerebellar nuclei. In MPFIM, a microzone consists of a set of modules controlling the same degree of freedom and is learned by only one particular climbing fiber. The modules in this microzone compete to control this particular synergy. Inside such a module there are three types of PC, which perform the computations of a forward model, an inverse model, or a responsibility predictor, but all receiving the same input. A single internal model i is considered to be a controller that generates a motor command τ_i and a predictor that predicts the current acceleration. Each predictor is a forward model of the controlled system, while each controller contains an inverse model of the system in a region of specialization. The responsibility signal weights the contribution that this model will make to the overall output of the microzone. Indeed, MPFIM further assumes that each microzone contains n internal models of situations occurring in the control task. Model i generates motor command τ_i , and estimates its own responsibility r_i . The feedforward motor command τ_{ff} consists only of the output of the single models adjusted by the sum of responsibility signals: $\tau_{ff} = \sum r_i \tau_i / \sum r_i$.

The **PCs** are considered to be roughly linear. The **MF** inputs carry all necessary information including state information, efference copies of the last motor commands, as well as desired states. Granule cells, and eventually the inhibitory interneurons as well, nonlinearly transform the state information to provide a rich set of basis functions through the **PFs**. A climbing fiber carries a scalar error signal while each Purkinje cell encodes a scalar output – responsibilities, predictions, and controller outputs are all one-dimensional values. **MP-FIM** has been introduced with different learning methods: its first implementations were done using gradient descent methods; subsequently, expectation maximization (**EM**) batch-learning, and hidden Markov chain **EM** learning were applied.

Comparison of the Models

Summing up, we can categorize the cerebellar models **CMAC**, **APG**, Schweighofer–Arbib, and **MPFIM** as follows:

- *State-encoder-driven models*: This kind of model assumes that the granule cells are on–off types of entities that split up the state space. This kind of model is best suited for, e.g., simple function approximation, and suffers strongly from the curse of dimensionality.
- *Cellular-level models*: Obviously, the most realistic simulations would be at the cellular level. Unfortunately, modeling only a few Purkinje cells at realistic conditions is an immense computational challenge, and other relevant neurons are even less well understood. Still, from the biological point of view this kind of model is the most important since it allows obtaining insight into cerebellar function on cellular level. The first steps in this direction were taken by the Schweighofer–Arbib model.
- *Functional models*: From the computer-science point of view, the most interesting models are based on functional understanding of the cells. In this case, we obtain only a basic insight of the functions of the parts and apply it as a crude approximation. This kind of approach is very promising and **MP-FIM**, with its emphasis on the use of responsibility signals to combine models appropriately, provides an interesting example of this approach.

Proprioceptive feedback is used for adaptation of the motor programs as well as for updating the forward model stored in the cerebellum. However, the Schweighofer–Arbib model is based on the view that the cerebellum offers not so much a total forward model of the skeletomuscular system as a forward model of the difference between the crude model of the skeletomus-

cular system available to the motor planning circuits of the cerebral cortex, and the more intricately parameterized forward model of the skeletomuscular system needed to support fast, graceful movements with minimal use of feedback. This hypothesis is reinforced by the fact that cerebellar lesions do not prohibit motion but substantially reduce its quality, since the forward model of the skeletomuscular system is of lesser quality.

77.3.4 Cerebellar Models and Robotics

From the previous discussions, it is clear that a popular view is that the function of the cerebellum within the motor control loop is to represent a forward model of the skeletomuscular system; but how can these models be used in control?

Our assumption is that the cerebellum stores motor primitive relationships, which can be recalled through a certain state (i. e., sensor plus cerebrum-directed goal) input. These motor primitives perform certain coordinated movements (*synergies*) to, e.g., intercept a ball with a tennis racket. A key property of the underlying spine-controlled musculoskeletal system, however, is that *voluntary movement can be easily interpolated* within the control realm of the spinal cord. With this we mean that the combination of two movement primitives that are *nearby* in the relevant sensor domain will lead to a good prediction. *In one possible interpretation, the spinal cord-based control of our muscular system is approximately linear or linearized through internal models* [77.87]. It allows the cerebellum to store or recall movements at any level of granularity, and get good enough results in unlearned areas. There are various papers which, in part, confirm this theory (e.g., *Osu* and *Gomi* show the linear relationship between muscle activation and joint stiffness [77.88] or Höppner et al. between grip force and stiffness [77.89]).

Does this understanding of the human control system help robotics? Biological control algorithms are certainly a result of slow feedback loops and the flexibility of the actuators. One may argue that, as robotic systems move towards their biological counterparts, the control approaches can or must do the same. There are many lines of research investigating the former part; Chaps. 11 and 75. It should be noted that the drive principle that is used to move the joints does not necessarily have a major impact on the outer control loop. Whether McKibben muscles, which are intrinsically flexible but bulky (*van der Smagt* et al. [77.90]), low-dynamics polymer linear actuators, or direct-current (**DC**) motors with spindles and added elastic components are used does not affect the control approach at the cerebellar level, but rather at the motor control level (cf. the spinal

cord level). Of key importance, however, are the resulting dynamic properties of the system, which are, of course, influenced by its actuators. Linearity of the low-level control system, as we find in biology, is a goal to

strive for. Yet technical systems can benefit from advanced modeling approaches, and equally good results can be obtained – yet at the cost of more complex sensing, computation, and less generalizability.

77.4 The Role of Mirror Systems

Area **F5** (frontal area 5) in the premotor cortex of the macaque contains, among others, neurons which fire when the monkey executes a specific manual action, e.g., one neuron might fire when the monkey performs a precision pinch, another when it executes a power grasp. (In discussing neurorobotics, it seems unnecessary to explain in any detail the areas like **F5**, **AIP** (anterior intraparietal sulcus), and **STS** (superior temporal sulcus) described here – they will function as labels for components of functional systems. To fill in the missing details see, e.g., *Rizzolatti et al.* [77.91, 92].)

77.4.1 Mirror Neurons and the Recognition of Hand Actions

A subset of these neurons, the so-called *mirror neurons*, also discharge when the monkey observes meaningful hand movements made by the experimenter, which are similar to those whose execution is associated with the firing of the neuron. In contrast, the *canonical neurons* are those belonging to the complementary, anatomically segregated subset of grasp-related **F5** neurons, which fire when the monkey performs a specific action and also when it sees an object as a possible target of such an action – but do not fire when the monkey sees another monkey or human perform the action. Finally, **F5** contains a large population of motor neurons that are active when the monkey grasps an object (either with the hand or mouth) but do not possess any visual response. **F5** is clearly a motor area although the details of the muscular activation are abstracted out – **F5** neurons can be effector-independent. In contrast, the primary motor cortex (**F1**) formulates the neural instructions for lower motor areas and motor neurons.

Moreover, macaque mirror neurons encode transitive actions and do not fire when the monkey sees the hand movement unless it can also see the object or, more subtly, if the object is not visible but is appropriately *located* in working memory because it has recently been placed on a surface and has then been obscured by a screen behind which the experimenter is seen to be reaching (*Umiltà et al.* [77.93]). All mirror neurons show visual generalization. They fire when the instrument of the observed action (usually a hand) is large or small, far from or close to the monkey.

They may also fire even when the action instrument has shapes as different as those of a human or monkey hand. Some neurons respond even when the object is grasped by the mouth. When naive monkeys first see small objects grasped with a pair of pliers, mirror neurons do not respond, but after extensive training some precision pinch mirror neurons do show activity, also with this new grasp type [77.94].

Mirror neurons for grasping have also been found in parietal areas of the macaque brain and, recently, it was shown that parietal mirror neurons are sensitive to the context of the observed action being predictive of the outcome as a function of contextual cues – e.g., some grasp-related parietal mirror neurons may fire for a grasp that precedes eating the grasped object, while others fire for a grasp that precedes placing the object in a container (*Fogassi et al.* [77.95]). In practice, the parieto-frontal circuitry seems to encode action execution and simultaneously action recognition by taking into account a large set of potential candidate actions, which are selected on the basis of a range of cues such as vision of the relation of the effector to the object and certain sounds (when relevant for the task). Further, feedback connections (frontal to parietal) are thought to be part of a stimulus selection process that refines the sensory processing by *attending* to stimuli relevant for the ongoing action (*Rizzolatti et al.* [77.52] and recall the discussion in Sect. 77.2.4). Recognition is then supported by the activation of the same circuitry in the absence of overt movement.

We clarify these ideas by briefly presenting the **FARS** model of the canonical **F5** neurons and the **MNS** model of the **F5** mirror neurons. In each case, the **F5** neurons function effectively only because of the interaction of **F5** with a wide range of other regions. We have stressed (Sect. 77.2.3) the distinction between recognition of the category of an object and recognition of its *affordances*. The parietal area **AIP** processes visual information to extract *affordances*, in this case properties of the object relevant to grasping it (*Taira et al.* [77.96]). **AIP** and **F5** are reciprocally connected, with **AIP** being more visual and **F5** more motoric.

The Fagg–Arbib–Rizzolatti–Sakata (**FARS**) model (*Fagg and Arbib* [77.97] and Fig. 77.6) embeds **F5** canonical neurons in a larger system. The dorsal stream

(which passes through **AIP**) can only analyze the object as a set of possible affordances, whereas the ventral stream (via the inferotemporal cortex, **IT**) is able to recognize what the object is. The latter information is passed to the prefrontal cortex (**PFC**) which can then, on the basis of the current goals of the organism, bias the choice of affordances appropriate to the task at hand. Neuroanatomical data (as analyzed by *Rizzolatti and Luppino* [77.98]) suggest that **PFC** and **IT** may modulate action selection at the level of the parietal cortex. Figure 77.6 gives a partial view of the **FARS** model updated to show this modified pathway. The affordance selected by **AIP** activates **F5** neurons to command the appropriate grip once they receive a *go* signal from another region, **F6**, of the prefrontal cortex. **F5** also accepts signals from other **PFC** areas to respond to working memory and instruction stimuli in choosing among the available affordances. Note that this same pathway could be implicated in tool use, bringing in semantic knowledge as well as perceptual attributes to guide the dorsal system (*Johnson-Frey* [77.99]).

With this, we turn to the *mirror* system. Since grasping a complex object requires careful attention to motion of, e.g., fingertips relative to the object, we hold that the primary evolutionary impetus for the mirror system was to facilitate feedback control of dexterous movement. We now show how *parameters relevant to such feedback* could be crucial in enabling the monkey to associate the visual appearance of what it is doing with the task at hand. The key side-effect will be that this feedback-serving self-recognition is so structured as to also support recognition of the action when performed by others – and it is this *recognition of the*

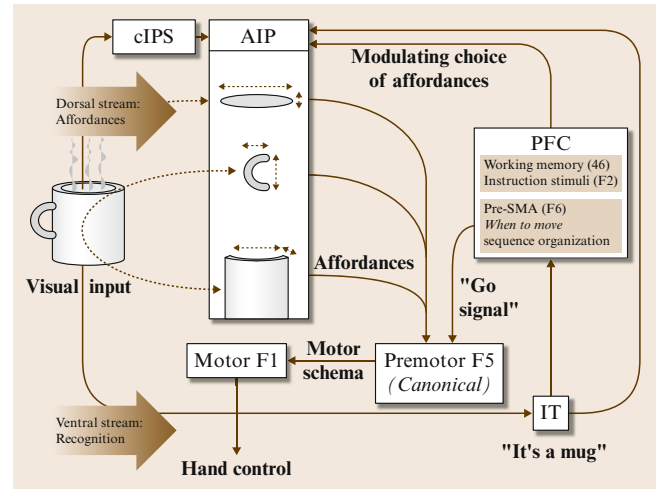

Fig. 77.6 The original **FARS** diagram (after *Fagg and Arbib* [77.42]) is here modified to show **PFC** acting on **AIP** rather than **F5**. The idea is that the prefrontal cortex uses the **IT** identification of the object, in concert with task analysis and working memory, to help the **AIP** select the appropriate affordance from its *menu*

actions of others that has created the greatest interest in mirror neurons and systems.

The **MNS** model of *Oztop and Arbib* [77.101] provides some insight into the anatomy while focusing on the learning capacities of mirror neurons. Here, the task is to determine whether the shape of the hand and its trajectory are *on track* to grasp an observed affordance of an object using a known action. The model is organized around the idea that the **AIP** → **F5_{canonical}** pathway emphasized in the **FARS** model (Fig. 77.6) is

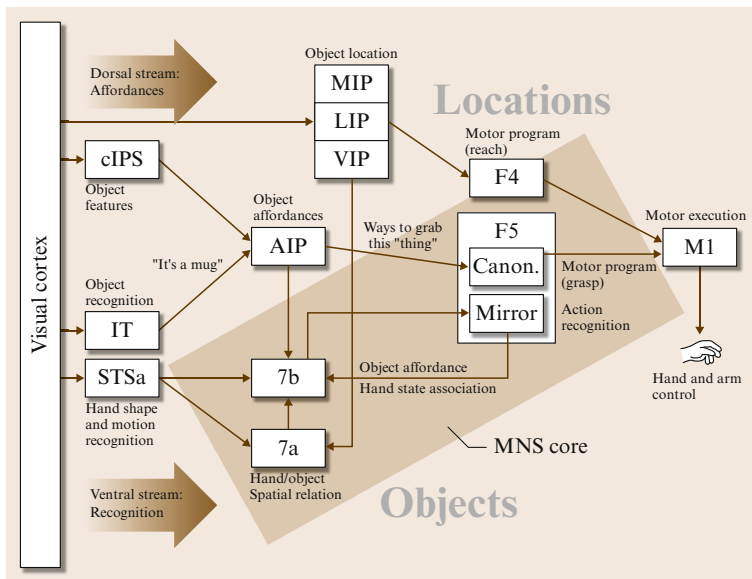

Fig. 77.7 The mirror neuron system (**MNS**) model (after *Oztop and Arbib* [77.100]). Note that this basic mirror system for grasping crucially links the visual process of the **STS** to the parietal regions (**b**) and premotor regions (**F5**), which have been shown to contain mirror neurons for manual actions

complemented by another pathway $7b \rightarrow F5_{\text{mirror}}$. As shown in Fig. 77.7 (middle diagonal), object features are processed by AIP to extract grasp affordances; these are sent on to the canonical neurons of F5 that choose a particular grasp. Recognizing the location of the object (top diagonal) provides parameters to the motor programming area F4 which computes the reach. The information about the reach and the grasp is taken by the motor cortex M1 (= F1) to control the hand and the arm. The rest of the figure provides components that can learn and apply key criteria for activating a mirror neuron, recognizing that the preshape of the observed hand corresponds to the grasp that the mirror neuron encodes and is appropriate to the object, and that the hand is moving on an appropriate trajectory. Making crucial use of input from the superior temporal sulcus (Perrett et al. [77.102] and Carey et al. [77.103]), schemas at the bottom left recognize the shape of the observed hand and how that hand is moving. Other schemas implement hand–object spatial relation analysis and check how object affordances relate to hand state. Together with F5 canonical neurons, this last schema (in parietal area 7b) provides the input to the F5 mirror neurons.

In the MNS model, the *hand state* was defined as a vector whose components represented the movement of the wrist relative to the location of the object and of the hand shape relative to the affordances of the object. Oztop and Arbib showed that an artificial neural network corresponding to PF and $F5_{\text{mirror}}$ could be trained to recognize the grasp type from the *hand state trajectory*, with correct classification often being achieved well before the hand reached the object, using activity in the F5 canonical neurons that commands a grasp as training signal for recognizing it visually; this basically shows that there is a causal relationship. Crucially, this training prepares the F5 mirror neurons to respond to hand–object relational trajectories even when the hand is of the *other* rather than the *self* because the hand state is based on the view of movement of a hand relative to the object, and thus only *indirectly* on the retinal input of seeing the hand and object, which can differ greatly between observation of self and other. Bonaiuto et al. [77.104] have developed MNS2, a new version of the MNS model to address data on audiovisual mirror neurons that respond to the sight and sound of actions with characteristic sounds such as paper tearing and nut cracking Kohler et al. [77.93], and on the response of mirror neurons when the target object was recently visible but is currently hidden Umiltà et al. [77.93]. Such learning models, and the data they address, make it clear that:

mirror neurons are not restricted to recognition of an innate set of actions but can be recruited to rec-

ognize and encode an expanding repertoire of novel actions.

The discussion of this section avoided any reference to imitation (Sect. 77.4.3). On the other hand, even without considering imitation, mirror neurons provide a new perspective for tackling the problem of robotic perception by incorporating action (and motor information) into a plausible recognition process. The role of the fronto-parietal system in relating affordances, plans, and actions shows the crucial role of motor information and embodiment. We argue that this holds lessons for neurorobotics: the richness of the *motor* system should strongly influence what the robot can learn, proceeding autonomously via a process of exploration of the environment rather than overly relying on the intermediary of logic-like formalisms. When recognition exploits the ability to act, then the breadth of the action space becomes crucially related to the precision, quality, and robustness of the robot's perception.

77.4.2 Computational Models

Roboticians have been fascinated by the discovery of mirror neurons and the purported link to imitation that exists in the human nervous system, for they can help to teach robots new tasks with relative ease. The literature on the topic extends from models of the monkey's (nonimitative) action recognition system (Oztop and Arbib [77.101]) to models of the putative role of the mirror system in imitation (Demiris and Johnson [77.105] and Arbib et al. [77.106]), and in real and virtual robots (Schaal et al. [77.107]). Oztop et al. [77.108] propose a taxonomy of the models of the mirror system for recognition and imitation, and it is interesting to note how different the computational approaches that have now been framed as mirror system models are, including recurrent neural networks with parametric bias (Tani et al. [77.109]), behavior-based modular networks (Demiris and Johnson [77.105]), associative memory-based methods (Kuniyoshi et al. [77.110]), and the use of multiple direct-inverse models as in the MOSAIC architecture (Wolpert et al. [77.111]; cf. the multiple paired forward-inverse models of Sect. 77.3.2).

Following [77.112], we can cast much that is known about the mirror system into a controller-predictor model [77.65, 113] and analyze the resulting model as a Bayesian classifier. As shown by the FARS model, the decision to initiate a particular grasping action is attained by the convergence in area F5 of several factors, including contextual and object-related information; similarly many factors affect the recognition of an action. All this depends on learning both direct (from decision to executed action) and inverse models

(from observation of an action to activation of a motor command that could yield it). Similar procedures are well known in the computational motor control literature [77.114, 115]. Learning of the affordances of objects with respect to grasping can also be achieved autonomously by learning from the consequences of applying many different actions to different parts of different objects.

However, how is the decision made to classify an observed behavior as an instance of one action or another? Many comparisons could be performed in parallel with the models for one action to become predominantly activated. There are plausible implementations of this mechanism using a gating network [77.105, 116]. A gating network learns to partition an input space into regions; for each region a different model can be applied or a set of models can be combined through an appropriate weight function. The design of the gating network can encourage collaboration between models (e.g., linear combination of models) or competition (choosing only one model rather than a combination). Reference [77.117] offers a similar approach to the estimation of the mental states of the observed actor, using some additional circuitry involving the frontal cortex.

On the other hand, if we take the Bayesian view of the predictor-controller formulation, then affordances are simply the priors in the action recognition process where the evidence is conveyed by the visual information of the hand, providing the data for finding the posterior probabilities as mirror neuron-like responses which automatically activate for the most probable observed action. Recall that the presence of a goal (at least in working memory) is needed to elicit mirror neuron responses in the macaque. We believe it is also particularly important during the ontogenesis of the human mirror system. For example, [77.118] has shown that even at 9 months of age, infants recognized an action as being novel if it was directed toward a novel object rather than just having a different kinematics – showing that the goal is more fundamental than the enacted trajectory. Similarly, if one sees someone drinking from a coffee mug then one can hypothesize that a particular action (that one already knows in motor terms) is used to obtain that particular effect. The association between the canonical response (object-action) and the mirror one (including vision) is made when the observed consequences (or goal) are recognized as similar in the two cases. Similarity can be evaluated following criteria ranging from kinematic to social consequences.

In a similar experiment *Lopes et al.* [77.119] compared action recognition performance (a) when using the output of an inverse visuo-motor model and thus

employing motor features to aid classification during the training phase, and (b) when only visual data were available for recognition. Overall, their interpretation of the results is that by mapping in motor space through inverse model mapping, they allow the classifier to choose features that are much better suited for performing optimally with respect to the task of recognizing actions, which in turn facilitates generalization. The same is not true when recognition is performed purely in visual space using generic visual features, since a given action is viewed from different viewpoints. One may compare this to the viewpoint-invariant hand state adopted in the *MNS* model – which has the weakness of being built in rather than emerging from training.

Along the same line, the work of *Gijsberts et al.* [77.120] included motorically-derived affordance information, which was recorded using a data-glove-based system and a set of cameras. In this case though, motor information was not much for action recognition but rather used to *simulate* the response of *F5*'s canonical neurons by generating discrete grasping types from the time-varying set of postures recorded with the data glove. After training the original motor information is removed and only reconstructed using an inverse model. Furthermore, this motoric information was combined with a simulation of the brain ventral pathway which extracts pictorial features from images (e.g., *SIFT* (scale-invariant feature transform), *H-Max*). The dorsal and ventral features were combined through a special kernel function in a simple least squares classifier, showing a significant improvement at recognizing objects in comparison to a purely visual classification. A machine learning framework to address the question of learning from multimodal signals (some of which can even be intermittent) is presented in [77.121].

We can speculate that this computational advantage (better recognition rates) makes the presence of mixed sensory and motor information compelling in the brain (i.e., the fronto-parietal system); this may not necessarily lead to mirror neurons although it seems plausible that any clear advantage of using information at best is eventually selected during evolution. These experiments, using robots, simulations, and computational arguments can thus explain the whys of certain brain structures and mechanisms.

77.4.3 Mirror Neurons and Imitation

Fitzpatrick and Metta [77.122] also addressed the question of what is further required for interpreting observed actions. Whereas in observing its own actions, the robot identifies them from the effects on the objects, later it could backtrack and derive the type of action needed to replicate a certain observed effect on a given object.

Therefore, imitation can be framed into the identification of a common goal between the observed action and various possible actions in the *motor repertoire* of the robot. In [77.122] the robot used the same visual processing algorithms both in observing its own hand and the hand of a person (although they were different in appearance). One might argue that observation alone can be used for learning, never relying on active exploration of objects and actions. This is possibly true to the extent that passive vision is reliable and action is not required. The advantage of the active approach, at least for the robot, is that it allows controlling the amount of information impinging on the visual sensors by, for instance, controlling the speed and type of action. This strategy might be especially useful given the limitations of artificial perceptual systems. Thus, observations can be converted into interpreted actions. The action whose effects are closest to the observed consequences on the object (which we might translate into the goal of the action) is selected as the most plausible interpretation given the observation. Most importantly, the interpretation reduces to the interpretation of the *simple* kinematics of the goal and consequences of the action rather than to understanding the *complex* kinematics of the human manipulator. The robot understands only to the extent it has learned to act. One might note that a more refined model should probably include visual cues from the appearance of the manipulator into the interpretation process. Indeed, the *hand state* that was central to the *Oztop–Arbib* model was based on an object-centered view of the hand's trajectory in a coordinate frame based on the object's affordances. The last question to address is whether a robot can imitate the *goal* of the action. The step is indeed small, since most of the complexity is actually in interpreting observations. Imitation can be generated by replicating the latest observed human movement with respect to the object utilizing one of the many approximation methods for motion generation such as, e.g., a mixture of Gaussians [77.123], dynamic motion primitives [77.124], or reinforcement learning [77.125]. More generally, following the work of *Schaal* et al. [77.107] and *Oztop* et al. [77.108] we can propose a set of schemas required to produce imitation:

- Determining what to imitate, inferring the goal of the demonstrator
- Establishing a metric for imitation (correspondence; see *Nehaniv* [77.126])
- Map between dissimilar bodies (mapping).
- Imitating behavior formation.

These are also discussed in greater detail by *Nehaniv* and *Dautenhahn* [77.127]. In practice, computa-

tional and robotic implementations have tackled these problems with different approaches and emphasizing different parts or specific subproblems of the whole, for example, in the work of *Demiris* and *Hayes* [77.128], the rehearsal of the various actions (akin to the aforementioned theory of motor perception) was used to generate hypotheses to be compared with the actual sensory input. It is then remarkable how more recently a modified approach of this paradigm has been used in comparison with real human transcranial magnetic stimulation (TMS) data.

Ito et al. [77.129] (not Masao Ito of cerebellar fame) took a dynamical systems approach using a recurrent neural network with parametric bias (RNNPB) to teach a humanoid robot to manipulate certain objects. In this approach the parametric bias (PB) encodes (tags) certain sensorimotor trajectories. Once learning is complete, the neural network can be used either to recall a given trajectory by setting the PB externally or provide input for the sensory data only and observe the PB vector that would represent in that case the recognition of the situation on the basis of the sensory input only (no motor information available). It is relatively easy to interpret these two situations as the motor generation and the observation in a mirror neurons model.

The problem of building useful mappings between dissimilar bodies (consider a human imitating a bird's flapping wings) was tackled by *Nehaniv* and *Dautenhahn* [77.127] where an algebraic framework for imitation is described and the correspondence problem formally addressed. Any system implementing imitation should clearly provide a mapping between either dissimilar bodies or even in the case of similar bodies when either the kinematics or dynamics is different depending on the context of the imitative action.

Sausser and *Billard* [77.130] modeled the *ideomotor principle*, according to which observing the behavior of others influences our own performances. The ideomotor principle points directly to one of the core issues of the mirror system, that is, the fact that watching somebody else's actions changes something in the activation of the observer, thus facilitating certain neural pathways. The work in question also gives a model implemented in terms of neural fields (see *Sausser* and *Billard* [77.130] for details) and tries to explain the imitative cortical pathways and the behavior formation.

77.4.4 Mirror System and Speech

Already in the 1960s *Lieberman* et al. [77.131] started to discuss the possible links between production and perception in speech: in other words the contribution of articulation into the perception of utterances. Later he commented [77.132]:

A result in all cases is that there is not, first, a cognitive representation of the proximal pattern that is modality-general, followed by a translation to a particular distal property; rather, perception of the distal property is immediate, which is to say that the module has done all the hard work.

Liberman argued that there is no such a thing as a modality-aspecific representation which then becomes speech as an effect of a translation to a specific set of articulators (the vocal apparatus in this case), rather, he claimed that perception of speech is immediate and effected by the same speech module (the same that generates speech); speech remains a motor fact. Lately, theories of the motor involvement in speech perception have gained credit because of the discovery of the mirror neurons. It has been postulated that the mirror system in humans *controls* jointly speech production and perception, whereby the actions in speech are the articulation of appropriate segments of the utterances [77.133].

We recall this line of reasoning in the following [77.133], that is:

- Mirror neurons (or a mirror system) exist in humans [77.134].
- The human mirror system is identified in Broca's area, a cytoarchitectonical homolog of area F5 in the macaque's brain.
- Speech articulation is coded/controlled in/by the areas of the human mirror system (Broca's) [77.135].
- The recognition of the intention of the speaker by the listener owing to a mirror mechanism leads to the first seed of true communication (via, e.g., orofacial gestures) [77.133].
- The combinatorial properties of F5/Broca and the precise control of the effectors are needed to generate speech (the evolutionarily older animal calls are too stereotyped to grant this flexibility that eventually leads to speech proper) [77.136].

To establish that this is the case, however, more empirical evidence is required. Recently, two experiments improved the plausibility of the mirror neurons theory of speech perception. In a first TMS experiment, Fadiga and colleagues [77.137] established that MEPs (motor evoked potentials) in the tongue muscles directly correlate with high specificity to the perception of particular sounds (these were *rr* and *ff* in Italian). The listener was delivered TMS (single pulse) and the observed MEPs correlated in amplitude with the different use of the tongue muscles for the pronunciation of either the *rr* or *ff* sounds (*rr* in Italian requires a strong mobilization of the tongue). Albeit convincing, this experiment leaves

open the question of specificity, since it can still be the case of a diffuse/generic activation of Broca's area.

A second experiment also by Fadiga et al. [77.137] was designed to set the issue. In this case, the TMS was delivered to the primary motor cortex with the aim of establishing a specific motor involvement into the perception of different sounds/phones. Two areas were individuated in the primary motor cortex as responsible to the lip and tongue movement, respectively (e.g., *p/b* sounds versus *t/d*). The data show a double dissociation pattern, that is, when the lip motor area is stimulated there is a decrease of the reaction times (RTs) of the subject in perceiving the *p/b* (labial sounds) and vice-versa an increase for the perception of the *t/d* (dental sounds). The opposite happens when the tongue motor area is stimulated. This experiment clearly relates a very specific (small) region of the primary motor cortex with the perception of certain specific (and related) sounds.

Clearly, this is only part of the story; to complicate matters, for example, the semantic content of words related to actions (e.g., kick, pick, lick) activate both motor and pre-motor brain areas somatotopically. Object features, odors, etc., instead have been shown to generate responses in the corresponding cortices. For a review of these and other results, see [77.136].

Theories and models such as the perception for action control theory (PACT) [77.138] take a more moderate interpretation by including both a motor component and *perceptual shaping*, that is, the filtering of certain linguistic combinations because of purely perceptual characteristics (e.g., separation of vowel formants). In PACT, it is hypothesized that the motor system is activated more in *adverse conditions*, while it is perhaps under-threshold for normal speech understanding in good signal-to-noise conditions.

Indeed, we can recognize speech in a foreign accent, and recognizing what is being said can then be decoupled from being able to articulate how it is being said – but both possibilities are available. This has led to a new view of the integration of mirror systems with other systems [77.139] which downplays the motor theory of speech perception while preserving many other features of the mirror system hypothesis of Rizzolatti and Arbib [77.133].

Armed with these results Castellini and colleagues [77.140] conducted a computational experiment that mimic some of the TMS results of D'Ausilio et al. [77.141]. All processing employed a database of synchronized recordings of Italian speakers with acoustic, articulograph, camera, ultrasound, and electroglottograph data [77.142]. For the experiments, only the articulograph and electroglottograph signals were used together with speech sound. These identify the position of the tongue and teeth versus the lips in

Fig. 77.8 Conceptual schema of the classifiers used in the experiments

Fig. 77.9 Baseline experiment comparing the performance of acoustic versus motor data (or jointly acoustic plus motor data) in classifying *b/p* versus *d/t*

real time (200 Hz) in addition to the activation of the vocal folds (voicing signal). The conceptual schema of all experiments and learning follows some previous work as by Metta et al. [77.112], and which as is shown in Fig. 77.8. In particular, acoustic data are mapped into motoric features and these are used for classifying phones. Similarly to the PACT model, it was found useful to incorporate also a purely acoustic classifier. Acoustic features were the standard Mel cepstral coefficients with similar parameters and frequency

bands of conventional automatic speech recognition (ASR).

The mapping from acoustic to motor data was performed using either an artificial neural network or support vector machine for regression with indistinguishable results. The classifier was always a support vector machine with Gaussian kernel and parameters optimized through grid search.

In order to compare it with the TMS experiments, phones were divided into two classes, the *b/p* and *t/d*, respectively, as representing the bi-labial and dental (movement of the tongue toward the teeth) phones. Fivefold cross-validation was employed on all results by either random splits of the data or by selecting data from various participants (e.g., training on 1–5 participants, testing on 1–5 participants). Gaussian white noise was added to the stimuli (at increasing levels from 0 to 150%) to replicate the conditions of the TMS.

Figure 77.9 shows these results. The baseline experiment shows an improved performance where either the real motoric or jointly motoric and acoustic features are used. The comparison of *audio* versus *joint* features is statistically significant ($p < 0.01$) and verifies the claim as no new information is added to the system when the reconstructed motor features are employed. Motor features are *reconstructed* by the audio-motor map (AMM) of Fig. 77.8 and replicates previous results obtained in the classification of hand gestures [77.119] or handwriting characters [77.143].

A second experiment from the same work of Castellini and colleagues [77.140] shows the behavior of the same system in various conditions of increased difficulty ranging from running classification on speakers not included in the training sets to co-articulation. Figure 77.10 shows a number of variants where N vs M indicates N speakers for training versus M speakers for testing given the size of the database (6 speakers). Ex-

Fig. 77.10 Comparison across various conditions. In all cases apart from coart4vs1 the use of motor features improve classification with statistical significance ($p < 0.01$)

Fig. 77.11 Comparison of acoustic versus motor features under increasing level of added Gaussian white noise for the same classifier of the previous experiments

periments with co-articulation were conducted also on five speakers, albeit the number of identifiable examples in the database was smaller.

In a final experiment, the classifier was tested on acoustic data corrupted by Gaussian white noise. Results show a consistent improvement with the motor information gain increasing with the increase of the noise level (up to 150% of the speech standard deviation): Fig. 77.11.

More recently a full phone classifier was built using similar principles [77.144] together with a combination of deep belief networks (DBNs) and more standard hidden Markov models (HMMs). The results show improvement with respect to the state of the art, continuing the long tradition of neurorobotics and bringing models very close to concrete applications on robots that bear resemblance to the exquisite human performance in speech recognition in noisy environments.

77.5 Conclusion and Further Reading

As the foregoing makes clear, robotics has much to learn from neuroscience and much to teach neuroscience. Neurorobotics can learn from the ways in which the brains and bodies of different creatures adapt to diverse ecological niches – as computational neuroethology helps us understand how the brain of a creature has evolved to serve *action-oriented perception*, and the attendant processes of learning, memory, planning, and social interaction.

We have sampled the *design* of just a few sub-systems (both functional and structural) in just a few animals – optic flow in the bee, approach, escape, and barrier avoidance in frogs and toads, and navigation in the rat, as well as the control of eye movements in visual attention, the role of the mammalian cerebellum in handling the nonlinearities and time delays of flexible motor systems, and the mirror systems of primates in action recognition and of humans in imitation. There are many more creatures with lessons to offer the roboticist than we can sample here.

Moreover, if we just confine attention to the brains of humans, this chapter has mentioned at least 7a,

7b, AIP, lateral, medial and ventral intraparietal sulcus (LIP, MIP and VIP), area 46, basal ganglia, caudoputamen, cerebellum, F2, F4, F5, hippocampus, hypothalamus, inferotemporal cortex, motor cortex, nucleus accumbens, parietal cortex, prefrontal cortex, premotor cortex, pre-SMA (F6), spinal cord, STS, and – and it is clear that there are many more details to be understood for each region, and many more regions whose interactions hold lessons for roboticists. We say this not to depress the reader, but rather to encourage further exploration of the literature of computational neuroscience and to note that the exchange with neurorobotics proceeds both ways: neuroscience can inspire novel robotic designs; conversely, robots can be used to test whether brain models still work when they make the transition from disembodied computer simulation to meeting the challenge of guiding the interactions of a physically embodied system with the complexities of its environment.

Nonetheless, a thorough study of the spinal cord and its effect on muscle behavior is where a roboticist, who is interested in replicating some of the functionality of vertebrate movement, may want to start looking.

77.5.1 Further Reading

- *Arbib* (2006) [77.145]: This volume provides 16 articles on the mirror system, written by diverse experts. Of particular relevance to this chapter are articles on dynamical systems: brain, body and imitation; attention and the minimal subscene; the development of grasping and the mirror system; and development of goal-directed imitation, object manipulation, and language in humans and robots.
- *Bell* (1996) [77.146]: This somewhat older BBS special issue provides what was, back then, a rather definitive number of articles on the cerebellum, including an overview of models in a paper by *Houk* et al.
- *van der Smagt* and *Bullock* (2002) [77.147]: This special issue is focused on the application of cere-

bellar and other models to robotics tasks, and lists some successful and – between the lines – more unsuccessful applications thereof.

- *Gallese* et al. (1996) [77.148]: This paper provides a detailed account of the neurophysiological evidence for mirror neurons. It is good reading to get the real data unbiased from further interpretation on the role of mirror neurons and it is complete and accurate. Although it is a technical paper it is easy to read also for a general audience.
- *Fadiga* et al. 2002 [77.149]: This work extends the mirror system concept with an interesting perspective on its role into language. This paper is interesting reading by providing evidence in humans (the other references above are about monkey experiments). In this case, it has been shown that speech listening facilitates the activation of tongue muscles which match the specific phoneme being listened to.

78. Perceptual Robotics

Heinrich Bülthoff, Christian Wallraven, Martin A. Giese

Robots that share their environment with humans need to be able to recognize and manipulate objects and users, perform complex navigation tasks, and interpret and react to human emotional and communicative gestures. In all of these perceptual capabilities, the human brain, however, is still far ahead of robotic systems. Hence, taking clues from the way the human brain solves such complex perceptual tasks will help to design better robots. Similarly, once a robot interacts with humans, its behaviors and reactions will be judged by humans – movements of the robot, for example, should be fluid and graceful, and it should not evoke an *eerie* feeling when interacting with a user. In this chapter, we present Perceptual Robotics as the field of robotics that takes inspiration from perception research and neuroscience to, first, build better perceptual capabilities into robotic systems and, second, to validate the perceptual impact of robotic systems on the user.

78.1 Perceptual Mechanisms of Object Representations 2097

The technical realization of perceptual functions is a central problem for many applications in robotics. Robots require perception to navigate in space and to localize and recognize goal objects, e.g., for manipulation (Chaps. 7, 8, 32, 33, 36–38, 47, 67). Social interactive robots must be able to interpret gestures, actions, and even emotions (Chap. 69, 71, 72) in order to interact naturally with their users. One important approach for the programming of complex perceptual and behavioral functions, for example, needed for humanoid robots is imitation learning (Chaps. 75, 77). Imitation learning requires the robot to *perceive* complex actions

that are executed by the user and to subsequently map them into an efficient representation that is suitable for the synthesis of the corresponding motor behavior on the available platform. This chapter focuses on important principles of the representation of complex shapes and movements, which can be derived from biological perception systems, and more specifically the basic functionality of the primate visual cortex. Such principles have interesting implications for the design of technical systems in robotics and computer vision for the recognition of objects, shapes and faces, and for the recognition and synthesis of complex movements and

actions. The limited space of the chapter forced us to focus mainly on visual perception and related technical applications. In the context of robotics many other aspects of perception are important, for example haptic perception (Chap. 41), auditory perception, sensory cue fusion (Chap. 35), and the interaction between the visual recognition of objects and actions and motor programs, e.g., during grasping (treated in Chap. 38).

In the following, we will first formulate several biological principles that are relevant for form and motion representations, specifically in the visual system. We will then, on the one hand, describe technical systems that implement these principles using neural mechanisms that are inspired by the basic architecture of the brain. On the other hand, we will discuss also implementations that are inspired by biological principles on a more abstract level, and which exploit instead of neural networks more efficient technical algorithms for the realization of biologically relevant functions. Many of these systems are derived in the field of computer vision and are based on the advantages and limitations of modern digital computers in order to more efficiently realize biological principles of information processing.

Our approach to establish relationships between biological perception and robotics systems at different levels reflects *David Marr's* classical distinction of multiple levels of description, originally developed for the analysis of vision systems [78.1]: Robotics systems can be inspired by biological system at the level of implementation, i. e., one can try to build robots containing neural mechanisms that imitate the function of neurons in central nervous systems of biological organisms. This type of analogy between technical and biological systems coincides with the definition of *Neurorobotics* given in Chap. 77. A transfer of principles from biological perception systems to robots might also be accomplished at the more abstract levels of computational problems and algorithms. The computational level is defined by the abstract theoretical formulation of computational problems that have to be solved by perception systems. Examples are the identification or classification of goal object, or the recognition of human gestures. Marr's level of algorithms specifies the computational methods for the solution of such problems, independent of the underlying specific hardware or architecture. For example, an object might be represented by modeling its full 3-D structure, e.g., using a parametric 3-D shape model, or it might be represented in terms of two-dimensional example views. Example views, however, might be represented using neural networks, establishing an analogy with the human brain at the level of implementation, or using more efficient computational methods, e.g., as support vectors of a classifier that has been trained with appropriate

images of the object and distractor patterns. In both the cases, the robot system realizes mechanisms that are derived from perception in biological systems.

Marr's distinction of levels is only one way to introduce description levels for complex systems. Other approaches, particularly relevant for robotics, are, for example the subsumption architecture and behavior-based approaches (Chap. 13) that decompose robotics system into a system of simpler behavioral modules. Another examples are dynamical systems approaches to robotics [78.2–4] that are based on the biologically motivated idea that behaviors can be mapped onto stable states of (nonlinear) dynamical systems or recurrent neural networks. Individual behaviors result by self-organization over the whole system as collectively stable modes, which can be described and analyzed by the introduction of appropriate collective variables. Interestingly, such robotics-inspired approaches have been quite successful in modeling human navigation behavior [78.5].

In the following, we will apply the term *Perceptual Robotics* to signify the design of robots based on principles that are derived from human perception on all three levels in the sense of Marr. This includes a realization in terms of specific neural circuits as well as the transfer of more abstract biologically inspired strategies for the solution of relevant computational problems. A direct interaction between robotics and perception research can be very fruitful for both disciplines. On the one hand, our current knowledge about the human perception and the underlying computational principles might help us to build more efficient robotics architectures that inherit properties from biological perception, e.g., very efficient and robust processing or complex dynamic flexibility. Such architectures will be a necessary pre-requisite for the creation of truly intelligent, cognitive robots (Chaps. 13, 71, 74, 75). On the other hand, perception science often uses robots as testbed for gaining a deeper understanding of computational processes, in particular, for testing the computational power of specific computational solutions under *real-world conditions*. How can a child, for example, learn how to handle new objects, and what allows us to learn the visual categorization of thousands of objects from just a few examples? *Perceptual robot platforms*, equipped with a variety of sensory inputs and operating in different types of artificially structured or real-world environments provide very helpful tools for the study of such questions.

Finally, perceptual robotics not only means to take inspiration from perception to build more efficient robots, but it also encapsulates the perceptual validation of robotic systems. As robots move into the human environment and are increasingly also interacting with

humans, it becomes important to evaluate and validate their effectiveness and efficacy with respect to human standards. Here, we do not refer to their social acceptance, but rather to the way that robots are judged by humans in terms of their appearance, movements, and interactive capabilities. If a robot displays jerky movements, for example, it may still successfully grasp and manipulate an object, but it would be immediately noticeable to a human observer and potentially disturbing to interact with. This *eeriness* or *weirdness* was already anticipated in the early 1970s in a famous paper about the *uncanny valley* by a Japanese roboticist [78.6]. Mori anticipated that as robots become more human-like, humans' familiarity with the robot would increase until at some point (when the robot looks or acts almost human-like), they would suddenly feel highly unfamiliar toward the robot. As the human likeness increases further, the robot would again be judged as familiar or appealing.

More specifically, Mori also postulated that this uncanny valley would not only hold for the robot's static appearance, but would in fact be increased for a moving or acting robot. With the increase in interest in develop-

ing humanoid robots over the past decades, being aware of the perceptual judgments of such humanoids becomes a critical component in their development. Since the evaluation of appearance and movements of a humanoid are driven by perceptual processes, it makes sense to also use protocols from perception research to evaluate and fine-tune their effectiveness. In such experiments, typically the robot's performance is evaluated with respect to measures such as general user acceptance, recognizability of expressions, smoothness of motions, ease of interaction, duration and quality of interaction, etc. It is important that the experiment should not only be about simply asking *how good is the robot*, but it should actually tests the robot in the intended task context or that whether it uses additional, indirect measures of effectiveness. As a tutorial on designing and analyzing perceptual experiments and user studies is beyond the scope of this chapter, we refer the reader to introductory texts such as [78.7, 8]. In this chapter, we will focus on two important topics related to humanoid perception in the context of perceptual robotics: facial animation and the perceptual processing of body movements.

78.1 Perceptual Mechanisms of Object Representations

Object recognition is a fundamental visual function that is critical for many applications in robotics. Manipulation and grasping (Chaps. 36–38) require exact knowledge about the shape of the goal object that is often derived from visual sensors. Also the imitation of goal-directed movements (Chap. 77) requires knowledge about target objects. Finally, social and collective robots require robust recognition of other agents and objects which are taking part in the present action (Chaps. 71, 72). The importance of object and shape recognition for many other applied robot systems, like construction and assembly robots or smart cars (Chap. 54) is immediately evident.

78.1.1 Perceptual and Computational Basis of Object Representations

The question of how humans learn, represent, and recognize objects under a wide variety of viewing conditions presents a great challenge to both neurophysiology and cognitive research. Frameworks for explaining the amazing robustness of human recognition processes and how humans represent objects can be broadly classified into two approaches: in the model-based representation, an image on the retina is analyzed to yield three-dimensional parts of an object based on geomet-

ric primitives (cf. also Chap. 32). These primitives are then matched to an internal, three-dimensional model of the object (Fig. 78.1, bottom). Exemplar-based representation approaches assume that the internal storage consists of, typically two-dimensional, snapshot-like representations of objects, which are directly compared to the visual input via simple image transformations. In the following, we will briefly describe the basic properties of these two approaches as well as perceptual evidence for their plausibility in explaining human recognition performance.

Structural Description Models

The basic idea of structural description models is that object recognition or categorization is based on a structural representation, which is defined as a configuration of elementary object parts that are regarded as shape primitives [78.9]. Structural description models aim at supplying abstract and propositional descriptions of objects, while at the same time disregarding irrelevant spatial information. Therefore, structural description models typically predict that recognition performance is invariant regarding spatial transformations. *Biederman's* recognition-by-components (RBCs) or geon structural description (GSD) model can be regarded as the best developed example of the struc-

Fig. 78.1 Schematic drawing comparing exemplar-based with model-based representations. Object perception based on model-based representations assumes that the brain extracts **3-D** parts from the visual image, which are then matched to an internally stored **3-D** model of the teapot. Contrasting with this approach, object perception based on exemplar-based representations is accomplished by directly comparing stored templates or example images with the current picture of the teapot

tural description model type [78.10]. According to this model, objects are represented as configurations of elementary three-dimensional primitive parts, called **geons**. These geons are derived from nonaccidental properties (**NAPs**) in the image, i. e., from properties which unlikely arise by chance, and are more or less invariant over a wide range of views. For example, the properties straight vs. curved, symmetrical vs. asymmetrical, parallel vs. nonparallel are regarded as **NAPs** (**NAPs** were originally proposed within an image-based approach by Lowe [78.11]). According to the model, geons and their spatial configuration are combined into a structural representation, called **GSD**. The spatial relations between parts are described in a categorical way, using relations like above, below, etc. Like other structural description models, Biederman's model predicts invariance in relation to position and size and also in relation to orientation in depth, as long as no parts are occluded.

The question has to be raised whether objects can be decomposed into geons at all. It was argued that Biederman's **RBC** cannot be applied to a whole range of biological stimuli [78.12], or that biological shapes in general cannot be adequately described by struc-

tural description models [78.13]. This problem extends also to artifact categories like shoe, hat or backpack, which seem to exceed the scope of the geon model. Therefore it has to be doubted that object parts are necessarily represented as geons, or as similar geometrical primitives (further problems of **RBC** in [78.14, 15]). However, this does not mean that category representations do not have a part structure: in fact, it is not the notion of the part structure in object representations by itself which is problematic, but the use of parts and relations as a basis to derive invariant recognition performance [78.15].

Exemplar-Based Models

Over the last two decades, an increasing number of studies has demonstrated that recognition is not view-independent. Orientation-dependent recognition effects were found for novel objects [78.16, 17], and also for common, familiar objects [78.18, 19]. Orientation-dependent recognition performance has been shown not to be limited to individual objects, such as faces [78.20, 21], or to objects on the subordinate level of categorization [78.16, 22], but also was demonstrated for basic level recognition [78.19, 23].

Moreover, recognition performance is not only influenced by the orientation, but also by the size of the stimulus. Results are quite similar: reaction times (RTs) and error rates depend on the extent of transformation that is necessary to align memory and stimulus representation. RTs increase in a monotonic way with increasing change of (perceived) size (for a review *Ashbridge and Perrett [78.24]*). Several studies even show a systematic relationship between the amount of translation and recognition performance: Increasing displacement between two sequentially presented stimuli led to a deterioration of performance, both for novel objects [78.25] and familiar objects [78.26]. Overall, view-independent models are difficult to reconcile with these findings which indicate that recognition performance depends systematically on different spatial transformations.

In the following, we will briefly review three types of exemplar-based models, which – by virtue of different computational mechanisms and processes (including alignment, interpolation, and pooling/thresholding) – explain the transformation-dependent performance that was found in the psychophysical experiments.

In the class of alignment models, *Ullman's [78.12, 27] 3-D alignment model* and *Lowe's [78.11] SCERPO model* are probably the best-known examples. Both models work by storing 3-D models of objects, which are aligned to images by perspective projection of corresponding features (edges or feature points on the object). As an alternative to *Ullman's [78.27] model* that relies on 3-D object representations, *Ullman and Basri [78.28]* suggested an alignment model on the basis of 2-D (two-dimensional) views. In this model, an internal object model is constructed by a linear combination of a small number of stored 2-D exemplar images. Thus, the alignment is not achieved by a spatial compensation process, but by linear combination of images. The intuition behind the linear combination approach can be explained in simple terms. Suppose that two views of the same three-dimensional object are stored, taken from somewhat different viewing directions. An intermediate view can then be described as a weighted sum of the views that are already stored. In this case, the representation is based on the two-dimensional positions of corresponding features in each view. Making the set of views closer results in an object representation that is equivalent to storing a 3-D model.

In the interpolation model, recognition is achieved by localization in a multidimensional representational space, which is spanned by stored views [78.29]. The interpolation model is based on the theory of approximation of multivariate functions and can be imple-

mented with radial basis functions (RBFs). In this scheme, the whole viewing space of an object is approximated by the learned exemplar views through a limited number of series of so-called radial basis functions (such as Gaussian functions) each of which becomes activated within a limited region of the high-dimensional feature space. Object recognition then means to examine whether a new point corresponding to the actual stimulus can be approximated by the existing tuned set of basis functions. Thus, recognition does not occur by transformation or reconstruction of an internal image, but rather by interpolation or approximation of exemplars in a high-dimensional representational space.

At the end of the 1990s – and as an extension to the interpolation models – recognition models based on pooling and thresholding were developed [78.30–33]. Recognition is explained on the basis of the behaviour of cells that are selectively tuned to specific image features (fragments or whole shapes) in a view-dependent (and size-dependent) way. A hierarchical pooling of the outputs of view-specific cells provides generalization over viewing conditions [78.30]. A similar proposal was made by *Riesenhuber and Poggio [78.31]*. The threshold model [78.34] also accounts for the systematic relation between recognition latencies and the amount of rotation (and size-scaling). The speed of object recognition depends on the rate of accumulation of activity from neurons selective for the object, evoked by a particular viewing circumstance. For a familiar object, more tuned cells will be activated in the views most frequently presented, so that a given level of evidence (threshold) can be achieved fast. When the object is seen in an unusual view, fewer cells will respond, and activity among the population of cells selective for the object's appearance will accumulate more slowly. Consequently, these threshold models explain orientation-dependence without the need to postulate transformation or interpolation processes.

In a recent paper, an attempt has been made at view-dependent and view-independent approaches to object processing [78.35]. A careful study of the view-dependency of novel objects was designed by combining structural properties (number of parts) with metric properties (thickness, size of parts) has found that both view-dependent and view-independent processing seem to be combined in object recognition. Thus, instead of taking the extreme standpoints of view-based versus view-invariant processing, one might envisage a visual processing framework in which features are selected according to the current task, where the optimality, efficiency and thus the dependency on viewing parameters of the features depend on the amount of visual experience with this particular task.

Several computational models have been proposed that aim at modelling and explaining the dependence of human recognition performance on spatial transformations in its complexity. All of these models rely on storing exemplars – in the simplest form just 2-D views of objects – and matching the retinal image to these stored examples by different computational methods. The later models of recognition take their inspiration from recent findings from physiological studies concerning the functional building blocks of human vision in the brain. In the following, we will therefore briefly review the neural processing of visual information in the brain that underlies our ability to recognize objects.

78.1.2 Neural Representations in Object Recognition

Functionally, it has been shown that the flow of visual information in the brain can be divided into two major pathways: the dorsal pathway is believed to process motion and motor- or action-related visual information, whereas the ventral pathway usually is associated with the task of object recognition. The structure of the ventral pathway is hierarchically organized and consists of a series of interconnected stages that start from the retina, passing through the lateral geniculate nucleus (LGN) to the primary visual cortex (V1) and extrastriate visual areas V2, V4, and IT. The inferotemporal cortex (IT) provides input to the prefrontal cortex (PFC), which is believed to play an important role in identification and categorization of visual stimuli. Recordings in the parietal cortex [78.36] suggest, in addition, that specifically for grasping and object manipulation also dorsal regions might be centrally involved in the recognition of manipulable objects and their affordances (Chap. 77 for a more detailed discussion).

The seminal work of Hubel and Wiesel [78.37] in the cat (and later also in the macaque) visual cortex first established the idea of a hierarchical organization of visual processing. They found so-called simple cells in the early visual cortex (area V1) that responded best to bar-like stimuli at a particular orientation and position in the visual field. The response pattern of these cells could be modeled as a receptive field using Gabor-type functions. Later in the processing stream they found so-called complex cells which responded best to bar-like stimuli at a particular orientation nearly everywhere in the visual field – cells, which had become partially position invariant. This general idea of increasing invariance to stimulus properties with later stages of the processing stream has been verified in further physiological studies. In general, it has been found that the receptive field of the neurons increases and that the complexity of

the stimulus it responds also increases. One of the key studies about the functional role of IT regions has investigated the responses of neurons to real-world objects in anesthetized monkeys ([78.38]; see also Tanaka [78.39] for a review). Although some neurons were found which responded maximally to simple bar-like stimuli, the majority of neurons in posterior inferotemporal cortex (PIT) preferred complex objects such as star shapes or circles with protruding elements. Interestingly, neurons were highly sensitive to minuscule changes to these objects such as the relative orientation or thickness of the elements. On the other hand, neurons were quite insensitive to stimulus variations such as size, contrast or retinal location. These findings were taken as evidence that one of the strategies for representing objects might be to use a number of moderately complex visual elements, whose pattern of co-activation encodes the visual appearance of the stimulus. In addition, Wang et al. [78.38] found neurons in anterior inferotemporal cortex (AIT), which responded maximally to images of whole objects such as faces or cars, indicating that already in IT object specific encodings might be present. Several other studies have also found neurons in this area which are tuned to faces, parts of faces, as well as body parts ([78.40] for a review).

In another set of experiments, Logothetis et al. [78.41] found AIT neurons, which showed a strong view-based behavior for the same stimuli that were used in the study of Bülthoff and Edelman [78.16], whereas they were invariant to size and location of the stimulus. Their findings provide strong evidence that a neural implementation of view-based object encoding is possible and indeed seems to be used for recognition. In addition to view-selectivity and size invariance, the investigated cells were also found to be maximally selective for the holistic stimulus rather than its constituent parts. This finding indicates that these cells might be encoding the pooled co-activation pattern of earlier PIT cells and thus form view-tuned units of recognition. It is important to stress in this context that an abstraction such as *grandmother* neurons, which specifically encode only one stimulus, does not seem plausible. Rather, the majority of neural responses in this and other experiments showed selectivity for a number of stimuli. A plausible explanation for this finding is that objects are encoded not by a single neuron but by a population code encompassing a number of neurons, which greatly increases the robustness of the representation [78.33].

The findings from this area of research can be summarized in a simple functional architecture: going from early stages to later stages of visual processing in a feedforward fashion, feature complexity increases from simple edge detectors toward view-tuned, com-

plex object cells and invariance to changes in the stimulus increases. This functional architecture is reflected not only in the object recognition framework discussed previously, but it also provides the motivation for computational vision systems that have been developed over the last few decades which will be discussed in the following.

78.1.3 Object Recognition: Lessons from Computer Vision

Computer vision started out as a subfield of artificial intelligence in the 1960s. Early work on scene understanding by *Roberts* [78.42] showed how computers could *parse* worlds consisting of simple, geometric objects such as cubes, pyramids, etc. The main thrust of computer vision systems in the following decades consisted of building algorithms for reconstructing a three-dimensional world from images – this development was further stimulated by *Marr's* very influential theory of vision as 3-D reconstruction [78.1]. This theory was built on extracting geometric primitives from images that could be mathematically described as generalized cylinders. Although the mathematical rigor of such approaches was very appealing, computational implementations turned out to have strong limitations. Extracting robust features is a necessary prerequisite for building a 3-D reconstruction of the image, and finding these features proved to be hard under real-world conditions due to the enormous amount of variation in the image caused by changes in lighting, depth rotations, noise, occlusion, etc.

Parallel to the paradigm shift in human psychophysics and physiology, exemplar-based computational systems began to emerge, which for the first time showed good recognition performance under a larger range of viewing conditions. These recognition systems were based on – sometimes surprisingly simple – histograms of pixel values [78.43], local feature detectors [78.44, 45] or on a straightforward pixel representation of images using principle components analysis [78.46]. All of these recognition systems relied on a database of labeled example images, an algorithm for extracting features from these images, and a suitable classification method for comparing sets of image features.

Returning to the discussion of modeling human vision, in the following we provide an exemplary review of three neuromorphic recognition systems that are based on a functionally plausible, exemplar-based architecture: these are SpikeNET [78.48], LeNet [78.49], and a framework by *Serre et al.* [78.50]. The first system is motivated by the finding that humans are amazingly fast at categorizing images as containing an animal or

a face [78.51]. Typical response times for this task are so small (on the order of 100 ms) that the visual signal has only time for one feedforward pass through the visual areas of the brain (Fig. 78.2) – any recurrent feedback processing would necessarily delay the decision and therefore result in longer response times. Based on this finding, a neural network architecture was designed [78.48] that exploits the timing of neuronal responses (spikes) to encode visual signals using a *who fires first* – strategy. This is different from traditional neural networks in that the timing is used rather than the firing strength. An object in this system will therefore be represented by an ensemble of neurons that represents a pattern of spike responses from earlier low-level, feature extraction neurons. In their implementation, these low-level neurons consist of standard Gabor-type receptive fields that are similar to the receptive fields found in the cat's visual cortex [78.37]. This spike time encoding allows for very fast processing of visual stimuli and has been shown to provide robust recognition results. The network ar-

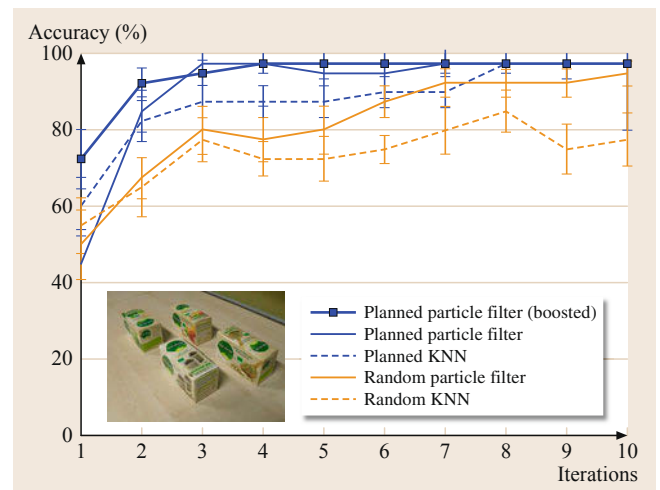

Fig. 78.2 Recognition performance of four highly similar object (shown in the inset) by an in-hand recognition system using active view selection (after [78.47]). The five methods compared in the plot contrast planned (blue) and unplanned (orange) exploration of the objects in the hand of the robot. The x-axis is the number of iterations, and the y-axis is the recognition accuracy in percent. As time (or iteration number) proceeds, the planned approaches surpass random exploration significantly. In addition, employing probabilistic methods for recognition of the objects using a particle filter also provides a recognition improvement. Finally, the *thick, solid blue line* shows performance in a system which boosts the likelihood of an object given the current visual evidence in the particle filter framework – this approach fares best overall. These results show that active view selection enhances the robot's ability to learn and recognize objects in real-world environments

chitecture LeNet [78.49] consists of a neural network that uses a hierarchy of layers of trainable convolutions and spatial subsampling, as well as nonlinear filtering to extract features of increasingly large receptive fields, increasing complexity, and increasing robustness. Using extensive, supervised training of the full hierarchy, such a network provides a very efficient, sparse set of features for many visual recognition tasks. Finally, the network architecture by *Serre et al.* [78.50] uses a very similar hierarchical structure of layers in which feature complexity and invariance are successively increased by linear and nonlinear pooling – its lower level feature detectors, however, are trained in an unsupervised fashion on a large database of natural images, yielding a large set of detectors that are optimally tuned to natural image statistics. Again, the performance of this model in recognition tasks has been shown to be very good – in addition, comparisons with physiological and psychophysical experiments have shown that this framework is also capable of modeling human results from these experiments.

Recent research has mainly focused on two topics: the automatic extraction of optimal visual features for efficient recognition and categorization, and the extension of the frameworks for providing invariance against changes in viewing conditions (such as rotations in depth, scaling, translation, illumination, and occlusion, for example, *DiCarlo et al.* [78.52], *Rolls* [78.53] for discussions of invariance in neuromorphic architectures). In a recent paper [78.54], these two issues have been addressed in a face recognition task conducted on a difficult database of faces taken in uncontrolled environments. The selection of optimal features was done by evaluating a large set of potential visual feature combinations using GPU-accelerated algorithms. The issue of invariance was addressed by using a hierarchical, multilayer model in which each layer includes linear and nonlinear pooling operations that encode the input image. The combined system was benchmarked against other standard feature-extraction methods and a *flat*, nonhierarchical one-layer model. Both properties resulted in increased recognition performance on the database outperforming other benchmarked state-of-the-art methods. In addition, the system also showed increased robustness against viewing variations, which included pose, position, scale, and background clutter.

In summary, neuromorphic architectures have now reached a stage of maturity that can put them even ahead of sophisticated, state-of-the-art computer vision frameworks. The ability to learn and adapt the feature set to viewing conditions and the increased robustness to viewing conditions makes such architectures good candidates for building the visual learning and recognition system for a perceptual robot.

78.1.4 Object Learning and Recognition for Perceptual Robotics

In general, it can be said that the success of perceptually inspired recognition systems can be seen as a strong indicator for the feasibility of a data-driven, exemplar-based approach to recognition. There are three issues, however, which so far have not been addressed in any of these vision systems and which will be important both for achieving human performance in generic recognition tasks in a perceptual robotics application – as well as for a full understanding of the processes in human object recognition.

First of all, all of the above-mentioned systems are feedforward – virtually no feedback, recurrent processing is implemented in their architecture, which makes them in a sense very similar to the simpler frog- or bee-like neural systems discussed in Chap. 77. Although there is evidence that humans solve some recognition tasks using very little feedback (see, e.g., *Thorpe et al.* [78.51]; *DiCarlo et al.* [78.52]), it nevertheless is a crucial component of visual processing driving, for example, attentional focus, context awareness, as well as memory and reasoning processes – basically everything that makes up visual *intelligence*. Some visual attention models that are relevant for robotics systems are reviewed in Chap. 77.

Secondly, a severe limitation of most of today's artificial recognition systems is that they solely focus on the static domain of object recognition. Visual input on the retina, however, consists of dynamic changes due to object- and self-motion, nonrigid deformations of objects, articulated object motion as well as scene changes such as variations in lighting, occluding, and re- and disappearing objects – where at any given point in time several of these changes can be interacting. Several psychophysical experiments, indeed suggest an important role for dynamic information, both in learning and recognition of objects [78.55–58]. These results ask for an extension of current object recognition frameworks with a temporal component in order to arrive at truly spatiotemporal object representations. Combining methods from computer vision, psychophysics, and machine learning, *Wallraven and Bülthoff* [78.59, 60], have developed a framework that fulfills this requirement and learns spatiotemporal, exemplar-based object representations from image sequences. More specifically, spatiotemporal characteristics of the visual input are integrated into a connected view-graph representation based on tracked local features. In order to provide robust classification performance, machine learning techniques are used to design efficient methods for combining support vector classification schemes with these local feature representations [78.61]. In sev-

eral studies it was shown that the framework achieved excellent recognition results on both highly controlled databases as well as on real-world data. The integration of spatiotemporal information provides characteristic information about dynamic visual input via the connection of views and the two-dimensional image motion of discriminative features. In addition to delivering good recognition performance, the framework was also able to model results from psychophysical experiments on face and object recognition. A similar model using a neuromorphic architecture integrating the temporal dimension was proposed by Kietzmann et al. [78.62].

A third issue that – in our view – will be essential for designing and implementing efficient perceptual robots consists of the multisensory nature of our perceptual system (see also the discussion of embodied robots in Chap. 13). As an example, there is a close coupling between the human visual and haptic system – touch can provide a wealth of complementary information about an object when it is manipulated, such as its texture, its shape, its position in space relative to our body, etc. In a series of psychophysical experiments [78.63], participants had to learn views of four simple, 3-D objects made of stacked toy-bricks either in the haptic modality (when they were blind-folded) or in the visual modality (without being able to touch them). Subsequently, they were tested both within the same modality as well as across modalities. Recognition results showed that cross-modal recognition is possible well above chance. Not surprisingly, recognition of rotated objects in the within-modality condition was severely affected by rotation in both modalities. This shows that not only visual recognition is highly view-dependent but also that haptic recognition performance is directly affected by different viewing parameters. The results from this experiment thus support the view that haptic recognition is also mediated by exemplar-based processes.

Taken together with the keyframe framework outlined above, this cross-modal transfer might be an important reason for the excellent visual performance

of human object recognition – after all, it is known that infants learn extensively by actively grasping and touching objects, which thus could provide a *database* of object representations for visual recognition [78.64]. Using this basic perceptual principle as a motivation [78.60] have applied an extension of the keyframe framework in an online robotics scenario for efficient learning and recognition of multisensory object representations. More specifically, a framework was developed to integrate both proprioceptive information originating from haptic sensors in the robot's hands and visual information coming from the robot's cameras. For this, the robot would perform an exploratory movement with an object in its hand (such as turning it and looking at it from all angles) and from the resulting image sequence learn spatiotemporal, view-based representations using the keyframe framework. Each view of this representation, however, is also linked to the current proprioceptive state (i. e., the joint angles of the hand at that point in time) and therefore provides an anchor into a hand-centered, three-dimensional space. In this way, a representation is generated that links perception and action. The proprioceptive information can then be used as an additional constraint for both learning of objects and recognition of objects and was shown to provide increased robustness compared to visual matching alone. The framework was also used as the basis for recent work in which a humanoid robot (the iCub) performed active in-hand object recognition, searching for the optimal view that allowed it to disambiguate the object currently held from other, previously seen objects [78.47]. Again, linking the exploratory actions (turning the hand) with the visual data resulted in a much faster and more reliable object recognition performance. Sample data comparing unplanned and planned recognition of difficult objects is shown in Fig. 78.2 (VIDEO 569).

Such approaches pave the way for a view of recognition as an active, multisensory process in which rich, extensible object representations are formed and improved over the life-time of the robot.

78.2 Perceptual Mechanisms of Action Representation

The recognition of complex movements and actions is fundamental for many applications in robotics, such as imitation learning by observation. Interactive robots need to analyze their users' movements in order to respond in a natural way to their social and emotional behavior (Chap. 72). The following section reviews what is known about movement and action recognition in the brain and tries to highlight a few aspects that have

or might be successfully transferred to biologically inspired applications in robotics and computer vision.

78.2.1 Recognition of Complex Movements and Actions in Primate Cortex

The recognition of complex movements and actions is a fundamental problem for higher animals and specif-

ically for primates. While simple movement patterns are sufficient for eliciting stereotypical prey catching behavior in simple vertebrates ([78.65]; see also Chap. 77), higher animals exploit more complex movement patterns, e.g., for the recognition of conspecifics or predators, or for communication by facial movements, gestures, or body expressions. Human perception of body motion patterns is very efficient, even for extremely impoverished stimuli. This has been demonstrated in classical experiments by *Johansson* [78.66], who showed that complex dynamic actions can be recognized even from displays that consist only of a small number of dots moving like the joints of a human actor. Subsequent research has demonstrated that humans can extract highly specific information from such *point-light displays*, e.g., the gender or the identity of people. To our knowledge, no technical system for motion recognition has been proposed so far that accomplishes a comparable level of robustness. While much more research in neuroscience has been dedicated to object recognition (Sect. 78.1.2), some studies have tried to uncover neural [78.67–70], and computational principles [78.71–73] of visual movement recognition. Some of these principles have been transferred to the construction of systems in computer vision and robotics.

Neurophysiological and brain-imaging studies indicate that the recognition of facial and body movements involves the ventral and the dorsal visual pathway. This implies that likely form and optic flow information are integrated during the processing of action stimuli in visual cortex. The ventral pathway, which is specifically responsible for the processing of form information has been discussed already in Sect. 78.1.2. Like the ventral stream, also the dorsal pathway is hierarchically structured, and the size of the receptive fields of the neurons increases along the hierarchy. Some cortical areas that are part of the dorsal pathway are listed in Fig. 78.3. The *medial temporal area* (MT) contains neurons that are selective for simple local motion and coherent motion. On higher levels of the dorsal stream, e.g., in the *superior temporal sulcus* (STS), neurons that are selective for hand and body movements and for facial expressions have been found in monkeys [78.69], and similar structures are activated by these stimuli in the human brain. In addition, areas selective for human body shapes, such as the *extrastriate body part area* (EBA), likely to contribute to the recognition of actions [78.74], where information of form and motion features seems to be integrated on higher processing levels [78.73].

For the recognition of goal-directed actions, such as reaching or grasping, in addition cortical structures beyond the visual cortex, such as the parietal and premotor cortex, seem to play a critical role. The role of these

structures for action recognition has been analyzed in particular in the context of the study of the *mirror neuron system* [78.75]. Mirror neurons are sensorimotor neurons that combine visual tuning during action observation as well as selective motor tuning. Areas in parietal cortex, such as the anterior might be specifically relevant for the recognition of action-related objects and their relationship to moving effectors [78.36]. Research about the mirror neuron system has influenced the construction of a whole generation of biologically inspired robots (Chap. 77). The guiding hypothesis has been that the visual recognition and *understanding* of actions is accomplished by mapping of observed body movements onto motor representations that are relevant for the execution of the same type of action.

78.2.2 Biological Principles with Relevance for Computer Vision and Robotics

We discuss in the following two major principles that have been derived from the analysis of action recognition in biological systems that have been transferred to technical applications in computer vision and robotics.

A first principle that seems to be implemented in movement recognition in primate cortex is a hierarchical architecture of feature detectors, which accomplishes action recognition by the detection of temporal sequences of relevant motion and form features. Such detection does not necessarily require the reconstruction of the three-dimensional facial or body shape, nor an exact simulation of the dynamics of the underlying movements. Instead it can be accomplished by much simpler computational mechanisms. Like object recognition, the recognition of complex motion patterns is strongly orientation- and view-dependent. This property has been observed at the level of individual neurons in the STS, and for the activation of biological motion-selective areas in human cortex [78.69] as well as for action-selective neurons in higher areas such as the premotor cortex [78.76]. View- and orientation dependence seem compatible with an encoding of visually perceived movements in terms of potentially learned example views, or *keyframes* (snap shots), and of instantaneous optic flow patterns that are characteristic for actions [78.67, 73]. While there might be some innate preferences for specific features [78.77], psychophysical and fMRI (functional magnetic resonance imaging) experiments suggest an important role of learning in visual movement recognition [78.78–80]. For example, subjects can learn easily to recognize individually – specific body and facial movements [78.81, 82]. Learning-based theoretical models, exploiting similar principles as neural object recognition models, account for a variety of experimental data on action

Fig. 78.3 Example-based neural model for the visual recognition of body movements that integrates the processing of form and motion features in the ventral and dorsal visual pathways (after *Giese and Poggio* [78.73])

recognition in biological systems [78.73, 83, 84], also supporting a central role of learning.

As an example of such a learning-based architecture, Fig. 78.3 illustrates a hierarchical model for the recognition of complex body movements [78.73]. It consists of two hierarchical streams modeling the ventral and the dorsal visual pathways, which contain detectors for action-specific motion and form features. The form pathway of this model is similar to the object recognition models described in Sect. 78.1.2. The motion pathway of the model contains detectors for action-specific optic flow features with different complexity. Like for the described object recognition models, position, and scale invariance is accomplished by appropriate nonlinear pooling of the responses of detectors with different spatial and scale selectivity along the hierarchy. In addition, the model contains recurrent neural circuits that make the responses of the recognition neurons selective for temporal order. In this way the model responds only to actions that are executed with the correct temporal order, and also with approximately correct speed. The underlying network dynamics can be interpreted as a neural implementation of a Markov model, where the present recognized pattern predicts

possible future patterns (Chap. 68). A strong activity in the network emerges only when the stimulus sequence matches these predictions.

Similar hierarchical neural architectures inspired by the visual cortex have been used in the context of mirror-neuron robot systems [78.85, 86]. In addition, recent work in computer vision shows that such biologically inspired architectures can reach very high performance levels, comparable to state-of-the-art algorithms in computer vision [78.87–89].

A second principle of movement recognition, which has been discussed extensively as basis for the recognition of imitable actions, and as explanation of the function of the mirror neuron system [78.75] is the idea that action observation is based on an internal simulation of the observed motor behavior. A variety of computational models for action recognition by internal simulation have been proposed in the neuroscience literature, e.g., exploiting feedforward controllers [78.90], coupled forward and backward models [78.91], hierarchical Bayesian predictive models [78.92], or a free energy minimization framework [78.93]. (A further more extensive discussion about theoretical models for the mirror neuron system with relevance for robotics

can be found in Chaps. 68 and 77.) A main difficulty of the recognition of actions by internal simulation of associated motor behaviors is the accurate estimation of relevant geometrical quantities from image data, especially when no special depth sensors or even online motion capture are available. Many of the underlying motor control models are formulated in joint angle space, and the robust recognition of joint angles from monocular videos is known to be a difficult computer vision problem, which so far is solvable only for highly restricted classes of movements with strong learned priors, and at considerable computational cost [78.94, 95]. This raises the question about simpler computational approaches for the recognition of goal-directed actions, which explain biological data and might be interesting for technical applications.

A recently developed model for the visual recognition of goal-directed hand actions in cortex that follows these lines [78.96] is illustrated in Fig. 78.4. The underlying architecture is an extension of the form pathway of the model shown in Fig. 78.3, by the addition of neural circuits that process the spatial and temporal relationship between the observed effector (in this case the hand) and the recognized goal object (e.g., a grasped object). The model works, exploiting a purely exemplar-based approach (Sect. 78.1.1), without explicit reconstruction of the three-dimensional structure of the object or the effector. The model comprises three modules: The first module (A, in Fig. 78.4) recognizes shapes of the goal object and of the effector,

implementing a shape recognition hierarchy similar to standard object recognition models as the ones described in Sect. 78.1.3. The analysis of the temporal deformation of the hand is based on the recognition of sequences of key shapes, like in the form pathway of the model in Fig. 78.3. Opposed to standard object recognition models, however, the highest level of this shape recognition hierarchy is not completely position-invariant. Rather, it retains coarse position selectivity by implementing multiple replica of the same shape detectors that are selective for different image positions. This makes it possible to further analyze the spatiotemporal relationship of the recognized goal objects and effector. This analysis is realized in the second module (B) whose core is formed by two-dimensional *relative position maps*. These are neural activity maps that represent the effector position as activity peak in a two-dimensional coordinate system that is centered on the object position in the image. These maps are computed by a gain fields [78.97] that multiply the output activities of shape selective neurons with selectivity for object and effector. The activity distribution in these neural map is analyzed by *affordance neurons* that are activated only when hand and object shape match and are in a spatial relationship that is suitable for a successful grip. By appropriate pooling of the responses of motion energy detectors that receive input from the relative position map *relative motion neurons* can be constructed, whose activity characterizes the relative motion between the effector and object

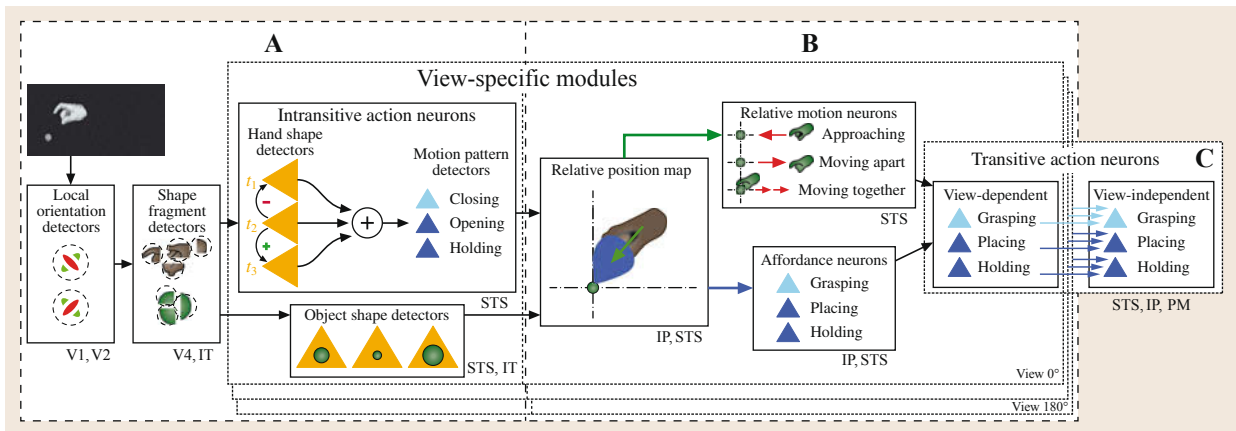

Fig. 78.4a–c Physiologically inspired model for the recognition of goal-directed hand actions. The shape-recognition (a) recognizes the shape of goal objects and the shapes of individual hand postures, retaining some coarse position information. The module (b) associates the information of hand and object by computing maps that represent the relative positions of hand and object in image coordinates. From these maps the spatial matching hand and object and their relative motion can be computed. The highest level module (c) contains model neurons that are selective for different types of goal-directed actions. Up to this level the model recognizes actions in a view-dependent manner, and only at the highest level (view-independent transitive actions neurons) the model accomplishes view independence by pooling the outputs from view-specific modules (courtesy of *Fleischer et al.* [78.96])

(e.g., the hand approaching the object). The outputs of affordance and the relative motion neurons are integrated in the third module (C), which contains only neurons that are selective for visually observed goal-directed actions. This integration of information is first accomplished in a purely view-specific manner. View independence is not established until the very last hierarchy level of the model that contains view-independent action-selective neurons. The idea of establishing view-dependence only very late in the cortical hierarchy seems counter-intuitive, and is at odds with several established computational models for action recognition. However, this dominance of exemplar-based representations until very high levels of the cortical processing hierarchy has been observed in electrophysiological experiments studying mirror neurons in premotor cor-

tex [78.76]. In this structure, which is traditionally associated with motor planning, the majority of mirror neurons is view-dependent and only a minority is view-independent. The discussed model can recognize hand actions from gray level videos. It could be augmented by integration of disparity or depth features, and by appropriate attentional control mechanisms that would make it more robust to cluttered scenes with multiple relevant objects. Whether similar architectures have advantages for the robust visual recognition of goal-directed actions in technical systems remains to be shown. Very recent work shows that such hierarchical deep architectures, which consist of learned feature detectors, outperform classical technical solutions on actual computer vision benchmarks for action detection [78.98].

78.3 Perceptual Validation of Robotics

Successful human–robot interaction is perhaps easiest when the robot offers interaction channels that are compatible to that of human–human interaction [78.99]. The most important interaction channels in this case are verbal and nonverbal communication with the face. Importantly, in human–human interaction, nonverbal communication using facial expressions, for example, constitutes up to 30% of the communicative content. Facial expressions are not only used to convey someone’s mood and emotion [78.100], but are also used in communicative contexts to signal understanding (a nod of the head), to modify what is being said (a raise of the eye-brows), and to control the conversational flow (a look of confusion may signal to the speaker to repeat what has been said). Hence, many humanoids have incorporated more or less sophisticated heads capable of producing human-like facial expressions and movements. Traditionally, this has been achieved using mechatronic implementations in which actuators drive facial features directly (e.g., as in the MDS robot by Lee and Breazeal [78.101]), or – in more complex implementations of android robots – mimic human muscle movements that are then used to deform artificial skin [78.102–104]. Other systems have used LEDs for displaying simple, changeable facial features (e.g., as in the iCub platform [78.105].

78.3.1 Realistic Faces for Robots

With such a great variety of robot systems also comes the need for an investigation of their perceptual evaluation and their interaction capabilities ([78.106] for such a study in the context of facial animations in

computer graphics). Indeed, one particular problem of android, human-like systems is that they easily could suffer from the uncanny valley effect as the actuators and/or the control framework cannot easily reproduce the smoothness of human facial expressions. A study of morphed images between a nonhuman robot face and a highly realistic android robot head, for example, clearly showed evidence of the uncanny valley effect [78.107] – a similar study for moving robot faces yielded more mixed results, but still showed that the most realistic robotic faces were clearly perceived as different from that of a human talking [78.108]. One solution for this is to change the robot’s appearance such that it stays away from close human likeness; however, conveying the full breadth of human communicative signals with different facial features, or a different facial topology may also be problematic. A different solution consists of avoiding a mechanical solution and instead resorting to facial animation from computer graphics. One example of such a system was presented in Delaunay et al. [78.109] in which facial animations are projected onto a rigid face mask. Since facial animation techniques are in many ways much more advanced, such a system allows for a more realistic and flexible interaction in human–robot interaction. Subtle cues such as eye-gaze, wrinkles, and other nonrigid facial deformations could be displayed via projection of an advanced facial animation engine. Initial perceptual experiments with such systems [78.109, 110] have yielded promising results. However, more studies need to be done to assess the properties of human–robot interactions in these and other implementations of facial displays.

Fig. 78.5 Stimuli used in experiment investigating the fMRI correlates of the observation of human and robot movements. The neural responses to the movements by a real human are compared with the ones induced by a human-looking robot (Android), and by a nonhumanlike robot (Robot) (after Saygin et al. [78.111])

78.3.2 Perceptual and Neural Processing of Body Movements of Robots

Research in humanoid robotics finally aims at optimizing the perceived naturalness or *human-likeness* of generated robot movements, since this in the long run will increase the acceptance of humanoid robots in social contexts. However, the present humanoid platforms have typically substantial constraints that still prevent the realization of complex really human-like movements. This is even more the case for the realization of behaviors on bipedal robots, due to the difficult problem to maintain dynamic balance (Chap. 67). Therefore, most body movements realized by present humanoid robots still differ in many aspects from human movements. This makes the quantification of the degree of realism of such movements presently a less pressing topic than the field of computer graphics, where psychophysical studies for the validation of the realism and quality of computer animation methods are meanwhile a standard [78.112–114]. However, research in psychophysics and neuroscience has started to investigate the differences between the perceptual processing of human and robot movements, and interesting results have been obtained that localize cortical subsystems that might be essential to distinguish human and nonhuman robot movements. A typical question in these studies has been which critical properties determine whether visual stimuli produce *motor resonance*, or an activation of action-selective neural structures. The results of such studies have not been completely consistent, since some studies found decreased activation of action-selective networks for robot movements [78.115–118] while others found no such differences [78.119]. Primarily visual processing areas responded sometimes more for robot movements than for normal human [78.111, 117].

The problem of such studies is that many factors might influence the perception and neural signals in action-selective areas, such as form, kinematics, and optic flow patterns. Typically, it is very difficult to control these parameters separately for real robots. In addition, the learning experience of observers with the specific robot might play an important role [78.120]. A recent study by Saygin et al. [78.111] tried to separate at least the influences of the robot appearance (shape) and the motion kinematics by comparing the fMRI signals (using an adaptation paradigm) driven by three different stimuli (Fig. 78.5): a real person (that served as model for the building of the robot), the human-like looking robot (*android*), and the robot without skin and surface parts that made it look human-like (resulting in very similar motion as the full robot). In visual areas (e.g., the extrastriate body area) the human and the human-like robot stimulus result in very similar activity. This is not true for the parietal cortex, which is part of the *mirror neuron network*. This region shows large differences between the human-like robot and the other two conditions, potentially reflecting an increase of neural processing resources that are required to cope with the contradiction between the form and the kinematic information that is presented by this stimulus. Opposed to this, the not human-like robot makes it expected that the motion is also not human-like, potentially causing no such conflict. Future studies of similar type, controlling for the different information channels of action processing (Sect. 78.2.2) as well as for the predictability of such stimuli dependent on previous learning, potentially combined with quantitative neural modeling, will be required to really understand how different factors are integrated in the neural processing of robot movements, and how this causes different levels of perceived *human-likeness*.

78.4 Conclusion and Further Reading

In this chapter, we have presented several principles derived from high-level cognitive processing in vision in the human brain that have been fruitful for

the development of systems in robotics and computer vision. The recognition of shapes and complex movements and actions is an important problem for many

applications in robotics. We have discussed a variety of results from neuroscience that indicate that these brain functions are likely realized by example-based representations. We have discussed neural implementations of such representations which partially have been tested successfully in the context of technical applications, and which are strongly inspired by the real cortical neural architecture. In addition, we have presented some new computational principles that seem to emerge from recent experimental results on the representation of goal-directed actions. Finally, we have discussed work that tries to use psychophysical and neuroscience methods for the validation of the appearance and the movements of human-like robots, and for the investigation of underlying neural mechanisms.

Example-based mechanisms for object and motion recognition account for the invariant recognition of complex patterns. However, they do not automatically extract the metric information about the object geometry, position and the spatial parameters of complex trajectories in world coordinates. For some tasks in robotics, like grasping, manipulation, or obstacle avoidance, such information is required (Chaps. 36–38, 47). For such tasks, example-based recognition must be fused with methods for the extraction of the relevant metric information. In robotics such information can be extracted by stereo vision or using special sensors,

like laser range finders. In the brain the fusion between such spatial information and information about objects occurs likely in parietal areas, like the anterior interparietal area (AIP) [78.121]. However, it is unclear whether the information about objects is only represented in terms of 2-D example views. Instead, it seems likely that also some form of 3-D information is encoded, potentially in an example-based manner. Also haptic and visual information about object shape might be merged in higher brain areas, e.g., in parietal and fusiform areas [78.122]. A further discussion about biologically inspired models for the extraction of action-relevant geometrical information in the context of grasping and manipulation is given in Chaps. 32 and 77.

The perceptual validation of the human-likeness and affective impact of humanoid robots likely will become increasingly important along with the further development of the technology that will increase the level of similarity between humanoid robots and humans. Likewise, it seems increasingly important to use quantitative methods from perception science to investigate the quality of the emotional and social interaction between robots and humans. We expect this to be a field where psychology can really contribute quantitative methods to engineering, reaching a level that goes beyond a qualitative and subjective comparison of *demos* which partially is still the standard in the field of humanoid robotics.
